ACKNOWLEDGMENTS

This dissertation is dedicated to my family: my grandfather, Howard P. Somers (1909-1981); my two daughters, Jennifer and Christine McLemore; my husband, James McLemore; and my grandparents Gordon Filbey (1908–1993) and Elizabeth Somers Filbey. Without their patience, encouragement, financial support, and enthusiasm this project would never have been completed. I especially owe gratitude to my daughters and husband who not only did not have much of a mother or wife for three and a half years, but fed me, washed my clothes, carried my rocks, and kept me company at home and in the field during that time. Thanks to Jim for repairing my equipment and providing me with support, money, and .equipment throughout this project. Although my grandfather, H. P. Somers, was not alive to .actively take part in this project, he and my grandmother taught me the skills and the attitude to finish and succeed.

This project was supported financially by the New Mexico Bureau of Mines and Mineral Resources (NMBMMR), Frank E. Kottlowski, former Director, and Charles E. Chapin, current Director and State Geologist. Their assistance and encouragement throughout are greatly appreciated. Scholarships provided by the Department of Geological Sciences, University of Texas at El Paso (UTEP) and the International Mining Days Scholarship enabled me to attend UTEP. A grant provided by Mount Royal Mining Co., John Ewing, president, provided additional financial support for this project. Financial support was also provided by my grandmother, Elizabeth Somers Filbey, and room and board was provided by Mr. and Mrs. Ed Carrier while I attended UTEP.

Many people assisted me with this project over the years. Steve Redd, Dewayne Johnston, and Bill Nielson of R&B Mining Co., current operators of the Center mine, allowed access to their mine as well as taught me about mining and grade control at this deposit. Leonard J. Taylor, president of Biron Bay Resources, Ltd., allowed access to the records and drill core of Biron Bay's Summit project. Discussions with Mr. Taylor and geologists Alexander Poe and Scott Klundt were extremely beneficial. Thomas Quigley, vice

iii

president of Great Lakes Exploration, Inc. provided data and drill core on the Alabama mine. Queenstake Minerals, Ltd. allowed access to data and drill core from the Jim Crow-Imperial mines. George Ryberg provided data and drill cuttings from the Carlisle mine. Douglas Hanson allowed access to his mines and data from the Carlisle and East Camp Group. Discussions with Paul Eimon concerning alteration and potential at Telephone Ridge were enlightening. Robert Appelt and William McIntosh provided paleomagnetic analyses that were vital to stratigraphic correlations.

-

<u>.</u>

The Smithsonian Institute, Washington, D.C. (Division of Petrology and Volcanology, Department of Mineral Sciences), allowed access to samples collected by Waldemer Lindgren in the early 1900s (NMNH 87905.0400-0404). Five samples were examined and thin sections made and are on file at the Smithsonian. The U.S. Geological Survey (USGS) Core Library, William Linenberger, provided working space and samples of the U.S. Bureau of Mines (USBM) drill core from the 1940s exploratory drilling project. Thin sections and data from that core are on file at the USGS Core Library in Denver, Colorado. I would also like to thank Roderick A. Hutchinson and several park rangers at Yellowstone National Park for discussions and tours of various hot springs and geysers at the Park.

Several people assisted me in the field at various times and their help and company were appreciated: Coralie Carrier, Jennifer and Christine McLemore, James McLemore, Lia Walker, Ron Lowery (Phelps Dodge, Inc.), Lynn Brandvold (NMBMMR), Douglas Jones, Robert Appelt, William McIntosh (NMBMMR), Thomas Quigley (Great Lakes Exploration, Inc.), Dave Hedlund (USGS), Jim Ratté (USGS), Philip Goodell (UTEP), Kenneth Clark (UTEP), Frances Julian (UTEP), Mark Ouimette, Randy Ruff, Daren Dresser, and Paul Eimon. Daren Dresser, David Bright and Douglas Jones assisted with sample preparation and computer applications. Chris McKee and Jacques Renault (NMBMMR) assisted with x-ray diffraction and fluorescence analyses. Lynn Brandvold and associates (NMBMMR) analyzed numerous samples for precious- and base-metals and mercury. Discussions with various individuals were helpful throughout the project, including Mike Pawlowski, Robert North, Sterling Cook and Ron Lowery (Phelps Dodge, Inc.), David Wahl, Bill Tipton (USBLM), Russell Schreiner (USBM), Pat Freeman (St. Cloud, Inc.), George Ryberg, Patrick Browne (University of Aukland, New Zealand), Donald White, Andrew Campbell (New Mexico Institute of Mining and Technology, NMIMT), George Austin (NMBMMR), Robert Eveleth (NMBMMR), Marc Wilson (NMBMMR), and Paul Eimon.

All or portions of this manuscript were reviewed by members of my committee, James McLemore, Douglas Hanson, Chris Beck, Robert Appelt, William McIntosh, Paul Eimon, Abe Gundelier, amd John Ewing.

Finally, a few special people have aided me and given of their time and deserve special recognition. I would like to thank my committee for their support and what they have taught me: Kenneth Clark, Nicolas Pingitore, Jerry Hoffer, Frances Julian, Roy Arrowood, and Charles Chapin. Coralie Carrier not only assisted me in the field but provided a home while I attended UTEP and has my gratitude. Discussions with George Ryberg were enlightening, however I especially enjoyed flying over the district and taking pictures from his airplane. Patrick Browne (Geothermal Institute, University of Auckland, New Zealand) was extremely helpful in discussing geothermal processes and alterations which aided my understanding of epithermal systems. I want to thank Ibrahim (Abe) Gundiler (NMBMMR) for his encouragement and advice, discussions on mineralogy, and providing SEM data on the ore minerals from the Center mine. Thanks also to Dr. Ruth Gross who taught me Spanish and enabled me to fulfill my language requirement. I also want to thank friends and classmates from UTEP and NMIMT (Mark Ouimette, Qingping Deng, Chris Beck, Lia Walker, Tanya Baker, Clara Podpora, Kevin Crain); together we got each other through! Thanks!

Lynne Hemenway typed this manuscript and Virginia McLemore, Kathryn Campbell, Rebecca Titus, and Michael Wooldridge drafted the figures and maps.

This dissertation was submitted to the committee on September 2, 1993.

ABSTRACT

The Steeple Rock district is one of several epithermal volcanic-hosted epithermal districts in southwestern New Mexico and southeastern Arizona. This area offers an excellent opportunity to examine the relationship between the distribution and timing of alteration and the formation of fissure veins in an epithermal environment. Five distinct types of vein deposits occur in the district: base with precious-metals, precious-metal, copper-silver, fluorite, and manganese. These veins are structurally controlled; hosted by Miocene to Oligocene volcanic, volcaniclastic, and intrusive rocks; and they appear to be spatially related to two types of alteration: alkali-chloride (propylitic to argillic to sericitic) and acid-sulfate (advance argillic). Mineralogic and chemical zonations, preserved textures, multiple horizons, stratigraphic relationships, and limited sulfur isotopic data are consistent with the acid-sulfate alteration being produced by acidic magmatic-hydrothermal fluids at temperatures less than 340° C in a relatively shallow environment (<1.5 km) such as a hot springs system. The acidic fluids are produced by disproportionation of sulfate in magmatic fluids with decreasing temperature as the fluids rose toward the surface. The epithermal fissure veins are younger than the acid-sulfate alteration as evidenced by cross-cutting, stratigraphic, and textural relationships, and age determinations. The epithermal veins were formed by low salinity (<5 eq wt% NaCl), slightly acidic to neutral pH fluids at temperatures between 240 and 320°C at relatively shallow depths (360-1300 m) and pressures (<150 bars) as evidenced by preserved textures, fluid inclusion data, mineralogy, and chemical composition. The alteration and mineralization in the Steeple Rock district occurred in response to cyclic volcanic activity and subsequent development of local hydrothermal systems in structurally-controlled areas of high heat flow. While the exact timing and duration of these events is unknown there is no evidence to support that these events were continuous; rather the alteration and mineralization were episodic, waning, and migrating from one locality to another. Economic potential for additional low-sulfidation, fissure vein deposits in the Steeple Rock district is excellent and potential also exists for the discovery of high-sulfidation, disseminated gold deposits,

÷

SUMMARY

The Steeple Rock mining district is located in the Summit Mountains in southwestern New Mexico and southeastern Arizona. An estimated \$10 million worth of gold, silver, copper, lead, and zinc have been produced from the district since 1880. In addition, minor quantities of fluorite, manganese, and decorative stone were produced. Most of the metal production was from the Carlisle (inactive) and Center (active) mines along the westnorthwest-trending Carlisle fault and the inactive mines along the East Camp-Summit fault. But more recently, Biron Bay Resources Ltd. (Toronto, Canada) has announced a discovery along the northwest-trending East Camp-Summit fault of 1.45 million tons of ore grading 0.18 oz/ton (6 ppm) Au and 10.3 oz/ton (353 ppm) Ag (press release, May 1992). Additional mineralized zones have been encountered in drill holes.

The district occurs in a tectonically complex region. It lies on the southern edge of the Mogollon-Datil volcanic field (late Eocene-Oligocene), on the northern edge of the Burro uplift, and near the intersection of the northwest-trending Texas and northeast-trending Morenci lineaments. Volcanic activity in the district occurred during mid-Tertiary extensional tectonics, but many of the regional faults have similar trends as older Laramide structures formed as a result of compressional tectonics. This suggests that reactivation of older crustal features may have occurred and may have controlled volcanic and geothermal activity. Rocks exposed in the Steeple Rock district consist of a complex sequence of Oligocene to Miocene (34 to 27 Ma) andesitic, basaltic andesitic, and dacitic lavas interbedded with andesitic to dacitic tuffs, sandstones, volcanic breccias, and rhyolite ash-flow tuffs which were subsequently intruded by rhyolite plugs, dikes, and domes (33 and 28–17 Ma).

Two distinct types of alteration occur in the district: (1) alkali-chloride (propylitic to argillic to sericitic to silicic) and (2) acid-sulfate (advanced argillic). At least three stages of alkali-chloride alteration affected the rocks: (1) regional premineralization, (2) localized synmineralization, and (3) regional post-mineralization. Alkali-chloride alteration is the most pervasive alteration type and is characterized by quartz, chlorite, and pyrite and a variety of

additional minerals depending upon host rock composition, permeability, composition of the fluids, temperature, and duration of the alteration process. Some of these additional minerals are temperature dependent: high-temperature assemblages (>200°C: epidote, illite, titanite, anhydrite), low-temperature assemblages (<200°C: smectite, illite/ smectite, dolomite, kaolinite, and mordenite), and low- to intermediate-temperature assemblages (chlorite, pyrite, calcite, adularia, illite, quartz).

.....

\$

 $\phi \to \phi$

۰.

• •

Several areas of acid-sulfate alteration which are superimposed and surrounded by alkali-chloride alteration have been mapped in the district. Three of these altered areas occur near epithermal veins, whereas the others are in the vicinity of mineralized faults. The acidsulfate altered areas are mineralogically, texturally, and probably temperature zoned and grouped into three types: (1) clay zone (outermost zone, lowest temperatures), (2) silicified zone (intermediate zone), and (3) massive silica/chert zone (innermost zone, highest temperatures). The clay zone is characterized by fine-grained, sugary, and vuggy to soft and friable textures. The silicified zone is characterized by fine- to medium-grained, massive to brecciated to vuggy textures. The clay and silicified zones are gradational and consist of kaolinite, quartz, hematite, pyrite, and locally alunite, pyrophyllite, anatase, diaspore, illite/smectite, illite, jarosite, and iron and manganese oxides. The quartz content increases from the clay zone to the silicified to the massive silica/chert zones. The massive silica/chert zone is characterized by massive, locally brecciated, quartz and/or chert, but no relict textures are preserved. Hydrothermal brecciation and hydrofracturing are common and suggestive of hydrothermal eruptions. The massive silica/chert zone consists of quartz with minor amounts of kaolinite, hematite, alunite, pyrophyllite, pyrite, and anatase. Some areas contain high gold anomalies. Examination of drill core reveals that these acid-sulfate altered zones are repeated at different intervals and are separated by areas of alkali-chloride alteration.

Five types of mineral deposits occur in the district: (1) base-metals veins with considerable gold and silver (5-20% base-metal sulfides), (2) precious-metals veins (<1% base-metals sulfides), (3) copper-silver veins (low gold), (4) fluorite veins, and (5) manganese

veins. A sixth type of deposit may also occur in the district: disseminated gold deposits associated with the acid-sulfate alteration. District wide zonation of epithermal veins is present. The base-metals veins occur along the west-northwest-trending Carlisle fault and may represent the center of the district. Fluid inclusion temperatures are highest in this area (240-325°C). Outward from the Carlisle fault, precious-metals veins occur along the northwest-trending faults. These veins grade into copper-silver veins locally. The veins in the eastern portion of the district along the East Camp-Summit fault are associated with calcite and fluorite, whereas the veins in the western portion of the district and manganese veins occur. Two or more centers of fluorite mineralization may exist on the basis of fluid inclusion temperatures. The epithermal deposits in the district are (1) low-sulfidation vein deposits, (2) structurally controlled, (3) younger than acid-sulfate alteration, and (4) deposited by low salinity (<5 eq. wt.% NaCl), slightly acidic to neutral pH fluids at temperatures between 240° and 325°C and at relatively shallow depths (360–1300 m). Faulting probably occurred throughout mineralization.

The alkali-chloride and acid-sulfate alteration probably represents a hot springs geothermal system, such as that at the Norris Geyser Basin in Yellowstone National Park. Some of the acid-sulfate altered areas were faulted and perhaps covered by younger volcanic rocks (34–27 Ma). Epithermal vein mineralization, along with associated symmineralization alteration and rhyolite intrusives, formed along the faults (28–18 Ma) after the acid-sulfate alteration. Locally, epithermal veins cut the acid-sulfate alteration, but elsewhere in the district, acid-sulfate alteration caps epithermal veins. Acid-sulfate alteration and epithermal mineralization alkali-chloride alteration.

÷...

The alteration and mineralization in the Steeple Rock district occurred in response to cyclic volcanic activity and subsequent development of local hydrothermal systems in areas of high heat flow. Timing and duration of these events is only speculative and based on a few age determinations and field relationships. There is no evidence to support that these events

were continuous; instead the alteration and mineralization were probably episodic, waning and migrating from one locality to another. Similar complex trends are observed in modern geothermal systems and other epithermal vein districts. The Steeple Rock district, other epithermal deposits, and modern geothermal systems have three similar controlling factors: (1) most occur in areas containing deep-seated intrusives that provide heat for convective hydrothermal systems consisting of meteoric and locally other fluids; (2) all are formed at shallow crustal levels; and (3) all are located along regional structures. Many ancient epithermal deposits occur in areas of modern geothermal systems. However, the Steeple Rock district is one example of the early development of a geothermal system with both alkali-chloride and acid waters followed by younger epithermal mineralization.

1. INTRODUCTION

1.1 Purpose

Epithermal mineral deposits have been recognized as an important class of mineral deposits for many years. Some of the largest gold and silver deposits in the world are epithermal deposits, including the "bonanza" gold deposits of the Comstock Lode and Sleeper deposit, Nevada; Creede, Colorado; and El Indio, Chile. There are many studies of epithermal deposits in the geologic literature, and several genetic models have been proposed (Buchanan, 1981; White, 1981; Hayba et al., 1985; Berger and Henley, 1989; White and Hedenquist, 1990). However, despite the large number of published reports, one of the current controversies in economic geology involves the relationship, classification, and genesis of precious-metal deposits, base-metal deposits, and associated alteration that occur in some fissure-vein, epithermal districts (Beane, 1991; Mango et al., 1991; Albino and Margolis, 1991; Margolis et al., 1991; Rye et al., 1992).

The main objective of this study is to determine how the distribution and timing of the alteration assemblage are related to the formation of precious- and base-metal veins in an epithermal environment. The Steeple Rock district in southwestern New Mexico and southeastern Arizona provides an opportunity to examine this relationship, because five distinct types of ore deposits occur in the district and they appear to be related spatially to two types of alteration assemblages (1) acid-sulfate (advanced argillic) and (2) alkali-chloride (propylitic to argillic to sericitic to silicic). Furthermore, district-wide variations in both alteration and mineralization also can be studied at Steeple Rock. The Steeple Rock district is also ideal for this study because of the three-dimensional (topographic relief as well as subsurface drilling data) and historical production data available.

In anticipation of identification of the contrasting but overlapping characteristics of these mineral assemblages, these data can be used to (1) provide geologic criteria in the Steeple Rock district to enhance successful exploration and development currently in progress, (2) determine the district zonation and genesis of the mineralization and alteration of the district, (3) provide an exploration model for epithermal deposits with similar characteristics to the Steeple Rock district, and (4) enhance current understanding of the processes involved in forming epithermal mineral deposits. A secondary objective of this study is to evaluate the economic resources of the Steeple Rock district.

1.2 Epithermal mineral deposits

Lindgren (1922, 1933) defined the term "epithermal" to include a broad range of deposits that formed by ascending waters at shallow to moderate depths (<1500 m), low to moderate temperatures (50°-200°C), and which are typically associated with intrusive and/or volcanic rocks. From fluid inclusion and isotopic data, it is now generally accepted that epithermal deposits were formed at slightly higher temperatures (50°-300°C) and relatively low pressures (few hundred bars). In addition, not all epithermal deposits occur in igneous rocks; for example, the Carlin-type deposits which are found in sedimentary rocks (Bagby and Berger, 1985; Berger and Henley, 1989). Work by White (1955, 1981) established the nowrecognized association between epithermal mineral deposits and active geothermal (or hot springs) systems. Subsequent work by Henley (1985) and associates (Henley and Brown, 1985) in New Zealand confirmed this association.

Epithermal mineral deposits occur in structurally complex tectonic settings that provide an excellent plumbing system for circulation of hydrothermal fluids. Numerous volcanic-hosted epithermal deposits occur along the margins of calderas (Rytuba, 1981), although other structurally complex volcanic settings, such as silicic domes and andesitic stratovolcanoes, are not uncommon for these deposits. It is important to note that not all calderas are mineralized (Rytuba, 1981). Only a few calderas in New Mexico contain epithermal mineral deposits (Fig. 1.1; North and McLemore, 1986, 1988).

Typical epithermal deposits occur as siliceous vein fillings, breccia pipes, disseminations, and replacement deposits in intermediate to silicic volcanic and volcaniclastic rocks. Common ore textures characteristic of epithermal deposits include: open-space and

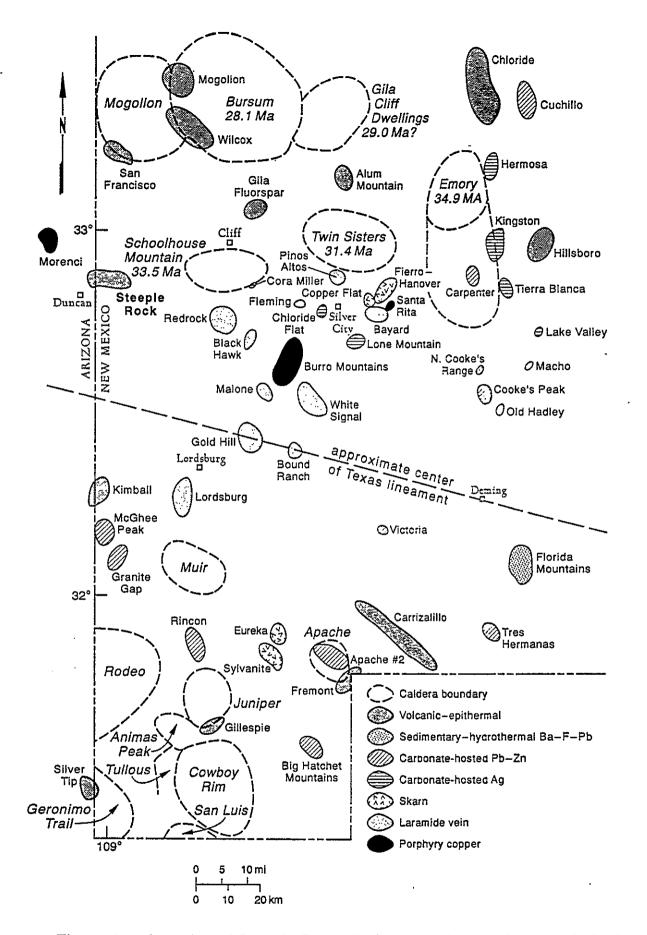

Figure 1.1 Location of Steeple Rock district in relation to other metal districts in southwestern New Mexico (modified from North and McLemore, 1986; McIntosh et al., 1992 a, b; NMGS, 1982)

cavity filling, drusy cavities, comb structures, crustification, colloform banding, brecciation (typically multi-stage), replacement, lattice (quartz pseudomorphs after bladed calcite), and irregular sheeting (Buchanan, 1981; Dowling and Morrison, 1989). The mineralogy and metal associations of these deposits are diverse and typically vary from one deposit to another. Both gold and silver are usually produced from these deposits with variable base-metal production. District zoning is also diverse, and in many districts precious metals occur in the upper levels of the epithermal system and grade into base metals at depth (Buchanan, 1981).

Hydrothermal systems undergo constant and, sometimes, abrupt physical and chemical changes. Equilibrium may never be achieved in these systems. This occurs as a result of (1)⁻ change from lithostatic to hydrostatic pressure (resulting in boiling), (2) changes in permeability, and (3) interaction of fluids derived at depth with near-surface, meteoric waters and host rocks of different lithologies. Consequently, fluid temperature, composition, and pressure are constantly changing.

The alteration mineral assemblage varies with changes in temperature, pressure, permeability, fluid composition, original host rock composition, and duration of activity (Silberman and Berger, 1985; Browne, 1978; P. R. L. Browne, written commun., 1992). Alteration assemblages include silicification, propylitic, argillic, advanced argillic, potassic, sericitic, illitic, and chloritic. This terminology is used to describe alteration that is associated with vein deposits in this study. Alteration assemblages reflect the composition of the prevailing fluid type and may also be referred to by the type of fluid as alkali-chloride, acid-sulfate, bicarbonate, or mixed fluids. This terminology is used to describe the regional alteration in this report. A clay alteration halo typically surrounds the deposits and in some areas the alteration is capped by a silicified zone or a sinter deposit, similar to deposits formed by active hot springs (Buchanan, 1981). Detailed clay analyses in some districts have defined the temperature of formation as well as general characterization and zonation of the mineralization and alteration. Studies by Hemley et al. (1980) suggest that the occurrence of pyrophyllite indicates alteration temperatures above 280°C. On occasion gold and silver are

closely associated with zonation of clay minerals (i.e. Golden Cross, New Zealand, DeRonde and Blattner, 1988; Pueblo Viejo, Dominican Republic, Vennemann et al., 1991). Studies by Yau et al. (1988) indicate a zonation of illite-muscovite (115–220°C) to chlorite (220–300°C) to biotite (310°C) with increasing depth in the Salton Sea geothermal field. Identification and recognition of this association of gold and alteration is important in identifying potential exploration targets.

Fluid inclusion analyses provide data on temperature of formation, salinity, and composition of the mineralizing fluids and may indicate a district-wide zonation of heat sources (Bodnar et al., 1985). Fluid inclusions sometimes show evidence of boiling (i.e. the presence of vapor-rich and vapor-poor inclusions). Boiling is one of the more popular mechanisms that have been invoked to explain the precipitation of gold from mineralized fluids. Precipitation of the metals could also occur by mixing of fluids and/or cooling. Most epithermal deposits formed at temperatures ranging from 50 to 300°C.

An important advance in the knowledge of epithermal mineral deposits occurred when Hayba et al. (1985) provided a two-fold classification of volcanic-hosted epithermal deposits based on mineralogy and associated alteration: adularia-sericite and acid-sulfate. In order to be consistent in terminology by defining both classes according to mineralogy, Berger and Henley (1989) refined this classification to adularia-sericite (illite) and alunite-kaolinite (\pm pyrophyllite). Earlier models referred to these deposits as quartz-adularia and quartz-alunite (Cox and Singer, 1986, model #25). One problem with applying this classification in the field is that some of the minerals, such as alunite, diaspore, adularia, etc., are too fine-grained to be identified easily (Berger and Henley, 1989). Thus White and Hedenquist (1990) refined this classification even further to low sulfidation and high sulfidation. The characteristics of each type are summarized in Table 1.1.

Hayba et al. (1985), Heald et al. (1987), Berger and Henley (1989), and White and Hedenquist (1990) provide convincing evidence that low-sulfidation (alkalie-chloride; adulariasericite) and high-sulfidation (acid-sulfate; alunite-kaolinite) deposits occur in separate and

5

TABLE 1.1—Characteristics distinguishing the low-sulfidation (adularia-sericite) and high-sulfidation (acid sulfate) epithermal deposits (from Hayba et al., 1985; Cox and Singer, 1986; Heald et al., 1987; Berger a Henley, 1989; White and Hedenquist, 1990).

•

distinct geochemical environments that rarely overlap. However, there are a few districts with characteristics of both low-sulfidation and high-sulfidation deposits (Heald et al., 1987; Beane, 1991), but these districts are rare and not well studied. The Steeple Rock district in southwestern New Mexico and southeastern Arizona (Fig. 1.1) appears to be an example of a district with characteristics of both low-sulfidation and high-sulfidation deposits, even though Berger and Henley (1989) classified the Steeple Rock district as a low-sulfidation (adulariasericite) epithermal deposit based on limited published geologic data.

1.3 Location, production, and exploration activity in the Steeple Rock district

The Steeple Rock mining district is in the Summit Mountains in Grant County, New Mexico and Greenlee County, Arizona (Fig. 1.1). The district derives its name from a prominent mountain peak, Steeple Rock (Fig. 1.2), in the southern part of the area. For the purposes of this report the Steeple Rock mining district refers to the entire area covered by Maps 1 and 2 (Figure 1.3) as well as some mines and prospects north and west of Maps 1 and 2. Other reports refer to various mining districts and subdistricts in the area; including Twin Peaks in the northern part of the mapped area (Biggerstaff, 1974; Keith et al., 1983), Bitter Creek district along Bitter Creek (Hedlund, 1990b), Duncan fluorspar district in the western part of the area (Hedlund, 1990b), and Goat Camp district west of Vanderbilt Peak (Keith et al., 1983). Some reports separate the Carlisle and East Camp into separate districts. It is appropriate to describe the area as one district because the geology is similar throughout the area and the various types of deposits are similar and possibly related to each other.

Exploration began about 1860, but production was not reported until 1880. An estimated \$10 million worth of metals were produced from the district between 1880 and 1991, which includes approximately 151,000 ounces of gold, 3.4 million ounces of silver, 1.2 million pounds of copper, 5 million pounds of lead, and 4 million pounds of zinc (Table 1.2). In addition, approximately 11,000 tons of fluorspar have been produced from the Mohawk, Powell, Leta Lynn, and other mines (McAnulty, 1978; Richter and Lawrence, 1983;

Hedlund, 1990b). In the Goat Camp Springs area, 2,000 tons of ore containing 74,500 lbs of manganese was produced, probably in the 1940s. Two rock quarries were opened and mined for decorative or building stone.

In the 1970s, 1980s and 1990s, exploration for gold and silver intensified and resulted in additional exploration drilling and some production, mainly for silica flux. Only one mine is operating in the district in 1993, the Center mine owned by Mount Royal Mining Co. However, at least three different exploration programs are under way. Great Lakes Exploration Co. drilled at the Alabama mine during July and August 1991 and Biron Bay Resources Ltd. is drilling along the Summit vein as part of their joint venture agreement with Nova Gold Resources Ltd. Weaco Exploration Ltd. drilled in the fall of 1991 at the Carlisle mine and is evaluating the mineral-resource potential of land adjacent to the Carlisle mine.

Figure 1.2—Steeple Rock, looking northeast. Note the spiral configuration giving its name that is formed by the rhyolite of Steeple Rock (age 33.1 Ma).

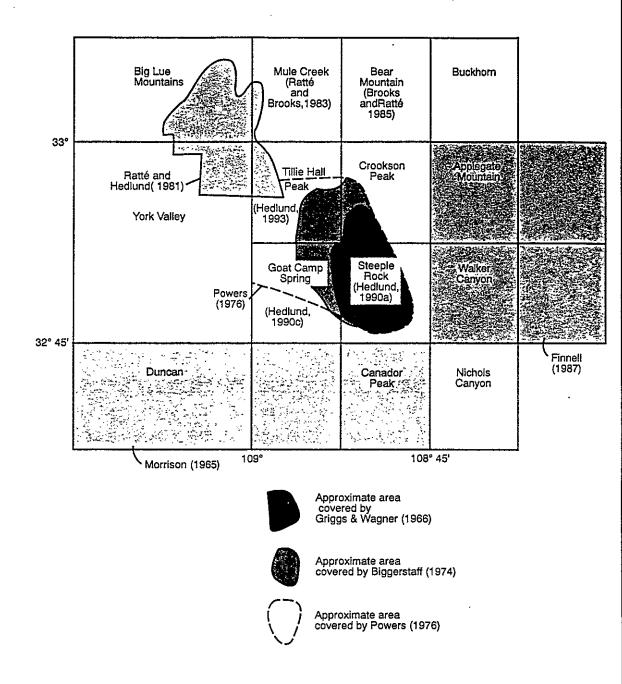

Despite this significant production and exploration activity, relatively minor detailed mineralogic and geochemical studies have been published on the Steeple Rock district.

1.4 Previous Work

The ore deposits were first described by Lindgren et al. (1910) who recognized that these deposits are epithermal. During World War II (early 1940s), the USGS and USBM examined the ore deposits along the Carlisle fault and conducted surface and underground mapping, drilling, and sampling as part of the national strategic minerals evaluation (Johnson, 1943; Russell, 1947; Griggs and Wagner, 1966). This investigation failed to locate any additional base-metal orebodies based on the economics at that time (Russell, 1947). The fluorspar deposits were described by Trace (1947), Wilson (1950), Williams (1966), Rothrock et al. (1946), and McAnulty (1978).

Geologic mapping of the area has been accomplished only in the last 30 years. Elston (1960) published a reconnaissance geologic map at a scale of 1:126,720 as part of the state geologic map compilation. The volcanic units were thought to be Cretaceous in age (Elston, 1956, 1961), but regional correlations and recent age determinations have confirmed a Mid-Tertiary age (Hedlund, 1990a,c, 1993; McIntosh et al., 1990a,b). Griggs and Wagner (1966) mapped the Carlisle-Center area.

More recent mapping includes several dissertations and theses which were completed as exploration for porphyry copper deposits intensified in southwestern New Mexico (Fig. 1.3; Wargo, 1959; Biggerstaff, 1974; Powers, 1976; Wahl, 1980). Of these theses, Biggerstaff (1974) presented the most detailed descriptions of the geology and mineralization of the district. Wahl (1980; 1983) also described the geology and mineralization in the Steeple Rock district and a few additional districts in western Grant County. Powers (1976) concentrated on the alteration within the district. In the late 1970s and early 1980s, regional reconnaissance geologic mapping of six quadrangles, including the Steeple Rock area, was completed as part of the Silver City CUSMAP project (Fig. 1.3; Tillie Hall Peak, Crookson

ŝ

Figure 1.3 Index to geologic mapping prior to this study. This area was mapped regionally by Elston (1960); Wahl (1980), Wargo (1959), and Drewes et al.(1985). The area covered on Maps 1 and 2 for this study is approximately the same area covered by Powers (1976).

Peak, Applegate Mountain, Goat Camp Spring, Steeple Rock, Walker Canyon, and parts of Canador Peak and Nichols Canyon); these maps were available to the author for this study (Hedlund, 1990a,c; 1993).

Areas surrounding the Steeple Rock district also have been mapped (Fig. 1.3). The geology of the Hells Hole RARE II planning area, north of the Steeple Rock district, was mapped by Ratté and Hedlund (1981). Several quadrangles adjacent to the district also have been mapped including the Mule Creek (Ratté and Brooks, 1983), Bear Mountain (Brooks and Ratté, 1985), and Cliff quadrangles (Finnell, 1987). Additional regional geologic mapping is by Morrison (1965) and Drewes et al. (1985).

Six abstracts have been published describing the mineral deposits and associated alteration of the district. Robinson (1984) and Eimon and Bazrafshan (1989) briefly describe the alteration and mineralization potential at Telephone Ridge, north of the Carlisle mine in the Steeple Rock district. Ruff and Norman (1991) present preliminary results of gas analyses of fluid inclusions from quartz samples from throughout the district: CO₂ and H₂S occur with some of the ore deposits in Steeple Rock. A thesis by Ruff (1993) updates these results. McLemore (1991) briefly described the mineralization and alteration of the district. McLemore and Quigley (1992) briefly described the mineralization at the Alabama mine, a low-sulfidation epithermal deposit. McLemore and Clark (1993) describe in more detail the mineralization and alteration of the district.

The mineral resources of the Hells Hole area were studied by Hassemer et al. (1983), Briggs (1981, 1982), and Ratté et al. (1982). Hedlund (1990b) briefly summarizes the geology of the mineral deposits in the Steeple Rock district. Sharp (1991) presents geochemical analyses of some igneous rocks in the district. Additional mineral resource reports briefly describe some of the mineral deposits in the Steeple Rock district and adjacent areas (Anderson, 1957; Gillerman, 1964; Hall, 1978; Richter and Lawrence, 1983; Wahl, 1983; Keith et al., 1983; North and McLemore, 1986, 1988; Richter et al., 1986; Tooker and Vercoutere, 1986; Raines, 1984; Watts and Hassemer, 1988). At least two remote sensing studies of the Steeple Rock district have been released. Raines (1984) identifies two limonitic areas in the district (Goat Camp Springs and Saddleback Mountain areas) on the basis of landsat color-ratio composite images. Magee et al. (1986) identify six areas of alteration (Saddleback Mountain, Goat Camp Springs, Telephone Ridge, Raeburn Hills, Laura-Alabama area, and East Camp area) using landsat thematic mapper imagery techniques. However, Magee et al. (1986) were unable to distinguish between acidsulfate alteration and silicification.

Numerous unpublished mine and exploration reports were obtained concerning the various mines and exploration projects in the Steeple Rock mining district. Many of these - reports include geochemical data, production data, and mine maps. This information was synthesized and utilized whenever pertinent. Individual reports and maps are referenced in this study as unpubl. report with the author and date noted. The reports are on file at NMBMMR.

1.5 Methods of Study

1.5.1 Geologic mapping and structural analysis

1.2

Detailed geologic mapping of altered areas and veins is necessary to determine the spatial relationships and timing of these events. Approximately 171 sq km were mapped in detail at a scale of about 1:12,000 and transferred to a map scale of 1:24,000. Standard U.S. Geological Survey 7¹/₂-minute topographic quadrangle maps (Goat Camp Springs, Steeple Rock, Crookson Peak, and Tillie Hall Peak; Fig. 1.3) were used as base maps. In addition, the eastern portion of the area was mapped at a scale of 1:4,800, using topographic base maps provided by Nova Gold Resources, Ltd. Outcrop mapping techniques were employed by locating actual outcrops on the geologic outcrop map (Map 1). Locations of mines and samples are on Map 2 and geologic cross sections are on Map 3.

Numerous mine adits and declines were mapped using a Brunton compass and measuring tape. The Center mine was mapped in more detail (Map 4); engineering surveys were available for some levels which provided better control.

Structural analysis of geologic data is important to determine the orientation of applied stress fields during deformation of the country rocks and to evaluate the possible relationship between structural style and timing of mineralization. Orientations of faults (281 measurements) and foliation and bedding planes (350 measurements) of various lithologic units were measured during the course of the field work. Locally, orientations of fault slickensides, joints, and fractures were also measured. These data were entered into QUATTRO PRO (Borland International, Inc., 1991). Stereonet plots were then constructed using the computer program STEREO (RockWare, Inc., 1992b). Unfortunately, many orientations could not be utilized in the structural analysis because only the strike could be measured in the field. The dip was not measured because of lack of exposure of the fault or foliation planes.

1.5.2 Drill core examination

Subsurface data provide the third dimension to this study. Diamond drill core from Jim Crow-Imperial mines (Queenstake Resources, Ltd.), Alabama mine (Great Lakes Exploration, Inc.), Carlisle-Center mines (USBM and R&B Mining Co. Inc.), Bitter Creek (Kennecott), and Summit project (Biron Bay Resources, Ltd.) were examined and logged (over 3600 m). Cuttings from reverse circulation drilling at the Carlisle mine (Weaco Ltd.) were also examined and logged. A binocular microscope and hand lens were used in examining the drill core. Samples were obtained for thin section preparation and geochemical analyses. A summary of pertinent drill core data is in Appendix 11.1.

1.5.3 Petrography and mineralogy

Petrographic analysis and mineral identification are important in differentiating various rock units, determining rank and intensity of alteration, determining chemistry of alteration fluids, and determination of paragenesis of mineralization. Alteration rank is based upon the mineral assemblages which infers temperature, pressure, and permeability conditions at the time of formation (section 5.1). Samples were cut and chips were sent to Spectrum Petrographics, Inc. for preparation of thin sections and polished thin sections. Petrography was performed using standard petrographic and reflected ore microscopy techniques. Mineral concentrations were estimated using standard charts (Swanson, 1981) and data are summarized in Appendix 11.2. Estimates of both primary and alteration minerals were determined and the alteration intensity was determined by the concentration of alteration minerals.

Altered, unaltered, and mineralized samples were powdered and analyzed by x-ray diffraction (XRD) at NMBMMR using pressed powder slides (Appendix 11.3). Some minerals with small sample volume were analyzed using a turbine drive sample spinner (Renault, 1984). Heavy mineral separates of high-grade gold-silver samples were obtained using a magnetic separator and gravity concentration. Clay minerals of many samples were determined separately using sedimented slide techniques of the $<2-\mu m$ size fraction (to eliminate or reduce non-clay minerals). All XRD analyses were determined using a Rigaku Geigerflex D/MAX series XRD unit with CuK α at 50 kV and 25 mA. Specific clay minerals were identified on randomly oriented powder packed into 2-mm-deep, side-loaded sample holders and examined using a Norelco XRD unit with CuK α at 40 kV and 25 mA. XRD results are summarized in Appendix 11.3.

Polished sections of heavy mineral concentrates from the Center mine were examined using a scanning electron microscope (SEM) by Ibrahim Gundiler (NMBMMR, metallurgist). Heavy metal concentrates were obtained by flotation methods described in Wilson et al. (1993; I. Gundiler and M. Brueggemann, written communication, May 25, 1990) and set in epoxy and polished. Samples were carbon-coated, degassed, and examined with a Hithachi hiscan HHS-2R model with an energy-dispersive x-ray spectrometer (EDS) at 20 Kv. All work was performed by Dr. Gundiler under the guidance of a technician at NMIMT and the results were made available for this study.

1.5.4 Geochemical and statistical analyses

Geochemical analyses of veins and rocks from the Steeple Rock district are important to (1) determine the composition of the magmatic systems and compare and contrast with known mineralized, magmatic systems, (2) determine the metal enrichment in the buried magma systems, (3) identify chemical zonations throughout the district, (4) characterize chemical composition of alteration and mineralization, and (5) determine potential for economic mineral resources. Samples of veins and country rock were collected in the field and submitted for geochemical analyses (Appendices 11.4, 11.5, 11.6). Locations of samples are on Map 2. Most field samples were grab samples, although some chip samples were also collected. Samples of drill core and drill cuttings were also collected, washed, and submitted. Samples were air dried, if necessary, crushed in a rock crusher to sand-size fragments and then powdered in a shatterbox. Powdered samples were split using standard splitting techniques (Obenauf and Bostwick, 1988).

Samples of veins and mineralized or altered country rocks were submitted to the NMBMMR Chemistry Laboratory (Lynn Brandvold, manager). Gold and silver were determined by fire assay techniques using one-half assay ton sample size (Hafty et al., 1977). Copper, lead, zinc, manganese, and iron were determined using aqua regia dissolution followed by analysis using atomic absorption spectrometry (American Public Health Association, 1992). Mercury was determined by cold vapor atomic absorption spectrometry using EPA method #245 (EPA, 1979). Fluorine was determined by sodium carbonate fusion followed by ion chromatography. Some duplicate samples as well as internal standards were included in the analyses. Commercial atomic absorption standards were obtained from Fisher Scientific and VWR Scientific and used in the analyses. AA analyses were performed on an instrumentation Laboratory Inc. AA (Model 857, Date 7/85) and instrument conditions were according to manufacturer's specifications using air-acetylene flame (Allied Analytical Systems, 1985, Methods manuel for flame operation). For example, Cu was determined using a wavelength of 324.7 nm, Pb a wavelength of 217.0 nm, and Zn a wavelength of 213.9 nm.

Table 1.3. Trace elements, method of analyses, and detection limits. (a) - % precision in fire assay of gold and silver is variable because of the nugget effect. (b) XRF is not the best method to analyze for Mo. Mo was analyzed to determine only if it occurred in large concentrations (> 100 ppm). 1 - From Lynn Brandvold (pers. commun. 9/23/93) and J. Renault and C. McKee (written commun. 5/11/93). Note that samples with analyses at or near the detection limits may have higher errors due to accuracy and precision—in some cases as much as 50%.

Samples of some veins, mineralized or altered country rock, and unaltered country rock were submitted to the NMBMMR x-ray facility (Jacques Renault and Chris McKee, managers). Major element oxides were determined by x-ray fluorescent spectrometry (XRF) on a Rigaku SYN 3064 model at standard operating conditions (Rigaku Manuel no. ME 300 BM) and using fused glass discs following the method of Norrish and Hutton (1969). USGS

rock standards were used to calculate the concentrations. Some major element oxides were determined by XRF using the fundamental parameters program of Criss Software (Criss, 1980). Trace elements were determined by XRF using pressed powder briquets (Obenauf and Bostwick, 1988).

Estimates of accuracy and precision are in Table 1.3. Errors due to accuracy were determined by multiple analyses of commercial standards for which acccepted values are known. XRF analyses utilized commercial standards consisting of BR (basalt) and GA (granite). AA analyses utilized SY-2 and SY-3 (Abbey, 1979). Errors due to precision were determined by multiple analyses of selected sample splits as well as multiple analyses of standard samples. In addition, Cu, Pb, and Zn were determined by both AA and XRF and the values were typically within 10% (Appendices 11.5 and 11.6).

Statistical analyses of chemical analyses determined for this study and of data sets provided by various companies are important in summarizing the data and ultimately in interpreting the significance of each data set. Each data set was statistically analyzed separately using RockStat (Rockware, 1991), MSTAT (Rockware, 1992a), and SPSS (Nie et al., 1975). Means, standard deviations, and correlation coefficients were determined where appropriate and factor analyses and discriminate analyses were employed. Petrologic calculations of major element analyses of unaltered and altered rock samples were obtained by using PETCAL (Bingler et al., 1976).

1.5.5 Paleomagnetic analyses

....

Paleomagnetic analysis of ash-flow tuffs (ignimbrites) is an acceptable, inexpensive, and rapid means of correlating compositionally similar ash-flow tuffs of different ages (McIntosh, 1991). A paleomagnetic study of ash-flow tuffs in the Steeple Rock area was undertaken by Robert Appelt in 1992. For this study, 236 oriented samples were field drilled from 37 sites. Sample locations are on Map 2. These data also include sites located by W. I. McIntosh from previous work. Samples were drilled in the field in situ using portable rock drills. Samples were then oriented by sun and magnetic compasses. The orientation of the paleo-horizontal was determined at each site using attitudes of pumice foliations, welding zones, and bedding contacts. Remnant magnetizations were measured using spinner and cryogenic magnetizations according to standard techniques described by McIntosh (1991). Demagnetization paths were analyzed using Zijderveld plots and principal component analyses to determine paths of univectoral decay and then processed using Fisher statistics to arrive at mean directions and alpha-95 confidence circles (Fisher, 1953; Kirschvink, 1980; Zijderveld, 1967). Acceptable alpha-95 data were set at $\leq 10\%$ confidence level. Robert Appelt performed all laboratory measurements and data reduction according to standard techniques described by McIntosh (1991). A paper is planned describing the results and significance of this study.

1.5.6 Fluid inclusion analyses

1999 **-**

Fluid inclusion analyses provide data on temperature of formation and chemistry of mineralizing fluids. Double-polished thin sections of 0.1 to 0.2 mm thickness were prepared by a commercial laboratory according to standard procedures. Homogenization temperatures (T_H) and last ice melting temperatures (T_M) of the fluid inclusions were determined by using a Fluid Inc. adapted USGS heating/freezing system assembled on a Leitz microscope. Duplicate measurements were run on all temperature analyses. The instrument was calibrated by fluid inclusion standards of pure water $(T_M = 0.0^{\circ}C)$ and $CO_2 + H_2O$ ($T_M = -56.6^{\circ}C$) provided by Fluid Inc. Periodic experimental runs were made using fluorite from the Hansonburg district with known T_H and T_M . The difference between temperature readings of repeated measurements in the same inclusion typically is less than 0.5°C. Fluid inclusion data are summarized in Appendix 11.7.

1.6 Units used in this report

For the most part, standard international or metric units are used in this report, with

20

one exception. All production and reserve figures are reported in English units of short tons and ounces per ton (oz/ton). The equivalent metric units are listed in parentheses adjacent to the English units. English units for production and reserve figures were used because the original data were reported in these units and the data may be incorrectly calculated when converting back from metric to English units. In addition, many American miners and some explorationists are more familiar with the English system. In order to be consistent, all chemical analyses were reported in a similar manner. Conversion factors are as follows:

4	1 short ton x $0.9 = 1$ metric ton
<i>/~</i>	1 troy ounce/ton (oz/ton) = 34.286 ppm
	3.281 ft = 1 meter (m)
	0.61 mile = 1 kilometer (km)

۰.

....

72

21

Data in the appendices and Map 2 are reported in English units in order to conserve space.

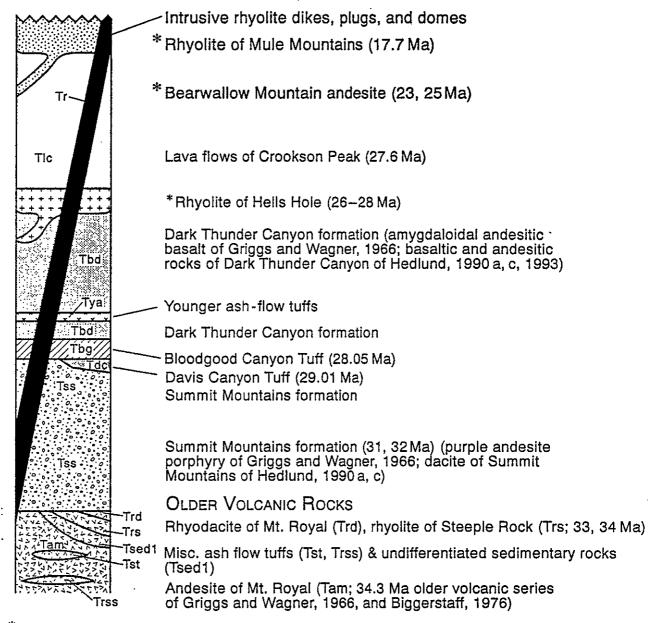

2. GEOLOGIC SETTING

2.1 General Statement

The Steeple Rock mining district lies in a tectonically active and structurally complex area of the southwestern United States that is known for numerous types of mineral deposits (Fig. 1.1). It lies in the Summit Mountains which are on the southwestern edge of the Mogollon-Datil volcanic field. The Mogollon-Datil volcanic field is part of a regional late Eocene-Oligocene volcanic province that extends from west-central New Mexico southward into Chihuahua, Mexico (McDowell and Claubaugh, 1979; McIntosh et al., 1990a, b). In southwestern North America, volcanic activity began about 40-36 Ma with the eruption of andesitic volcanism and, subsequently, episodic bimodal silicic and basaltic andesite volcanism followed from 36 to 24 Ma (Cather et al., 1987; Marvin et al., 1988; McIntosh et al., 1990a, b). About 25 high- and low-silica rhyolite ignimbrites (ash-flow tuffs) were erupted and emplaced throughout the Mogollon-Datil volcanic field during this event; source calderas have been identified for many of the ignimbrites (McIntosh et al., 1990a, b, 1992a). At least six of the ignimbrites crop out in the Steeple Rock mining district as outflow sheets. There is no structural or lithologic evidence to support the presence of a caldera in the Steeple Rock district, contrary to earlier interpretations (Biggerstaff, 1974; Elston, 1978). Subsequent faulting and volcanism have offset and covered portions of the ignimbrites making regional correlations difficult. Paleomagnetic analyses and radiometric age dating have aided in correlating the ignimbrites. Generalized stratigraphy of the Summit Mountains is shown in Fig. 2.1.

The Summit Mountains are situated within a transition zone between the Colorado Plateau to the north and the Basin and Range province to the south and west (Fig. 2.2). The prominent structural trend in the Summit Mountains is northwest, which subparallels the westnorthwest-trending Texas lineament of Wertz (1970a,b), Lowell (1974), Chapin et al. (1978), and Muehlberger (1980). The Summit Mountains lie on the northern edge of the Texas lineament. The northeast-trending Morenci lineament of Chapin et al. (1978) lies north of the

22

* Rocks not exposed in Steeple Rock district

Figure 2.1 Generalized stratigraphy of the Summit Mountains (modified after Hedlund, 1990 a, b, c, 1993). See Table 2.1 for compilation of age dates.

j.

Steeple Rock district. The Summit Mountains also lie on the northwestern edge of the Burro uplift.

The Steeple Rock mining district is one of several epithermal vein deposits found in southwestern New Mexico (North and McLemore, 1986, 1988) and southeastern Arizona (Keith et al., 1983) and is one of the few major epithermal districts not associated with any caldera (Fig. 1.1). Several porphyry copper deposits of Laramide age (>50 Ma) occur in southwestern New Mexico and southeastern Arizona, such as the Morenci deposit located about 48 km northwest of the Steeple Rock district (Figs. 1.1, 2.2).

2.2 Stratigraphy

2.2.1 Introduction and nomenclature

Although the Steeple Rock district is highly fractured and faulted, stratigraphic relationships are partially preserved. The oldest volcanic rocks (33-34 Ma) crop out in the southernmost portion of the area and the volcanic rocks decrease in age to the north and northeast (Maps 1, 2; Hedlund, 1990a, b, c, 1993; Ratté and Hedlund, 1981; Biggerstaff, 1974). The volcanic rocks in the mapped area range in age from 34 to younger than 27 Ma (Table 2.1). However, on an outcrop scale, the stratigraphic relationships in the Steeple Rock area are complex and are difficult to correlate in some areas. The andesites and dacites, especially where altered or weathered, are similar in appearance and difficult to differentiate. Likewise, the ash-flow tuffs are difficult to distinguish locally. Field relationships, petrography, whole rock geochemistry, and paleomagnetic analyses were utilized to decipher the local stratigraphy.

In simple terms, the volcanic activity in this area consists of successive periods of basaltic andesitic to andesitic to dacitic volcanism (about 2000-3000 m thick) that was periodically interrupted by the intrusion of rhyolites (Fig. 2.1; Table 2.1). At least four ash-flow tuffs (or ignimbrites) were erupted from distal calderas and the outflow sheets extended as far as the Steeple Rock area. These ash-flow tuffs provide excellent stratigraphic markers

*NOTE: The fission track data show large variations. The accepted age of the Bloodgood Canyon Tuff is 28.05 ± 0.01 and the accepted age of the Davis Canyon Tuff is 29.01 ± 0.11 based on ⁴⁰Ar/³⁹Ar on sanidines from throughout the Mogollon-Datil volcanic province (McIntosh et al., 1990a, b).

in the mapped area. The local volcanic stratigraphy is summarized in Figure 2.1, and Figure 2.3 is a simplified geologic map of the area. Some age determinations of rocks within and adjacent to the mapped area are reported in the literature and are summarized in Table 2.1.

Wherever practical, the stratigraphic nomenclature used in this study is the same as that established by reconnaissance regional mapping by Hedlund (1990a, b, c, 1993). He refers to two units as the dacite porphyry (or dacitic and andesitic rocks) of Summit Mountain and the basaltic and andesitic rocks of Dark Thunder Canyon. For the purposes of this study, these two units have been simplified to the Summit Mountain formation and the Dark Thunder Canyon formation. It is hoped that these two units will be formalized as formations in the future because they are the two major units that host economic mineralization. But, it must be emphasized that the usage in this study does not conform to standard U.S. Geological Survey nomenclature. The older literature refers to these units (and other units) in very informal terminology. Wherever possible, both Hedlund's nomenclature and the terminology in the older literature are correlated in this study (Fig. 2.1). Map symbols for each unit used on the map are in parentheses.

The classification of igneous rocks used in this study is that recommended by the International Union of Geological Sciences (LeMaitre, 1989). However, most rocks in the Steeple Rock area are altered and in some areas rock terminology was defined on the basis of both petrography and chemical analyses. Wherever possible, the precursor rock-type was defined. Terminology describing the grain size, crystallinity, crystal shapes, and textures of igneous rocks follows that described by MacKenzie et al. (1991). Terminology and classification of the sedimentary rocks follows Scholle (1979). Alteration is briefly mentioned in the following section, but more precisely described in section 5. A summary of petrographic descriptions is in Appendix 11.2.

TABLE 2.2—Paleomagnetic data from Steeple Rock area ash-flow tuffs. Units are listed in order of decreasing age. Explanation: inc, dec and int are site-mean inclination, declination, and intensity; k is Fisher (1953) precision parameter; α_{33} is radius of cone of 95% confidence.

÷.,

mean remanence data for each site are in Figures 2.4. Paleomagnetic data for each site are summarized in Table 2.2. For more details concerning potential problems utilizing paleomagnetic data, the reader is referred to McIntosh (1991).

From this study at least six different ash-flow tuffs are distinguishable in the Steeple

2.2.2 Paleomagnetic studies

Ash-flow tuffs (ignimbrites) provide excellent time-stratigraphic markers throughout the Mogollon-Datil volcanic field (McIntosh, 1991). Some of these flows extend as far as 140 km from their source caldera and provide stratigraphic markers within otherwise indistinguishable andesite flow sequences. However, regional correlations of many ash-flow tuffs are difficult at best because of disruption by regional faulting during Basin and Range extensional deformation. In addition, lithologic and geochemical similarities between different ash-flow tuffs and within the same ash-flow sequence hamper regional correlations (Hildreth and Mahood, 1985; Bornhorst, 1980, 1986, 1988). High precision ⁴⁰Ar/³⁹Ar geochronology of ash-flow tuffs have yielded precise age dates of ash-flow tuffs within the Mogollon-Datil volcanic field enabling correlation of various tuffs (McIntosh et al., 1990a, b, 1992a, b). However, there are problems with ⁴⁰Ar/³⁹Ar dating of ash-flow tuffs. Some tuffs do not contain useable, unaltered sanidines suitable for dating. Furthermore, ⁴⁰Ar/³⁹Ar dating is too expensive and time-consuming to be used on an outcrop to outcrop scale (McIntosh, 1991). However, paleomagnetic studies, especially where used in conjunction with detailed mapping and regional ⁴⁰Ar/³⁹Ar dating is an acceptable, inexpensive method for correlating ash-flow tuffs because of known magnetic reversals and secular variations of the magnetic field.

In the Steeple Rock area, numerous outcrops of ash-flow tuffs occur innerbedded throughout the Summit Mountain and Dark Thunder Canyon formations. These ash-flow tuffs typically occur near the contact of the Summit Mountain and Dark Thunder Canyon formations, are similar in appearance and composition, and difficult to correlate. Stratigraphic relationships are ambiguous in many areas. Preliminary paleomagnetic analyses by W. C. McIntosh (pers. commun. 1990) indicated the presence of three or four tuffs in the mapped area. Therefore, a paleomagnetic study of ash-flow tuffs in the Steeple Rock area was undertaken by R. Appelt in 1993.

Combined data from both McIntosh's and Appelt's studies were utilized to correlate various outcrops of ash-flow tuffs in the Steeple Rock area. Stereographic projections of site-

Rock area (Fig. 2.5). The oldest tuffs are two units within the older volcanic rocks of Steeple Rock (Tst, Trss, both known as the ash flow tuff of Steeple Rock; Hedlund, 1990b). Only one of these tuffs (Tst) occurs in the mapped area. The other tuff is to the south (Trss; Hedlund, 1990b). The Davis Canyon Tuff (Tdc) is the next oldest and has been dated elsewhere in the Mogollon-Datil volcanic field at 29 Ma (Table 2.1; McIntosh et al., 1990a, b). These three tuffs occur only in the southern portion of the mapped area. The Bloodgood Canyon Tuff (Tbg; Fig. 2.1) lies unconformably on the Davis Canyon Tuff in the southern area and lies unconformably on the andesites of the Summit Mountain formation elsewhere. It has been dated as 28 Ma (McIntosh et al., 1990a, b). The Bloodgood and Davis Canyon tuffs have different paleomagnetic characteristics, which distinguish them from a group of one or more overlying ash-flow tuffs, called younger ash-flow tuffs (Tya; Fig. 2.1) for the purposes of this study. The younger ash-flow tuffs typically occur at or near the base of the Dark Thunder Canyon formation and have a normal paleomagnetic polarity. The Davis Canyon and Bloodgood Canyon Tuffs have a reversed paleomagnetic polarity (Table 2.2, Fig. 2.4). The younger ash-flow tuffs are tentatively correlated with one or more tuffs in the Boot Heel field in southern New Mexico that have an age of about 27 Ma. Correlations of these younger ashflow tuffs are currently under study (W. C. McIntosh, pers. comm. 1993). There may also be ash-flow tuffs associated with the rhyolite domes and plugs; these tuffs are designated Tya3 in Figure 2.4. Any outcrops of ash-flow tuffs of questionable origin are designated Ta. A summary of the correlation of the ash-flow tuffs in the Steeple Rock area is in Figure 2.5.

2.2.3 Pre-Oligocene rocks

The oldest rocks in the immediate vicinity of the Summit Mountains area are Proterozoic in age. Small outcrops of coarse-grained, equigranular, locally porphyritic granite occur in the Riley Peaks area of the Canador Peak 15-minute quadrangle, south of Steeple Rock (Morrison, 1965). The granite is weathered and consists of feldspar, quartz, biotite, and accessory minerals. It is similar in appearance and composition to the Proterozoic granite

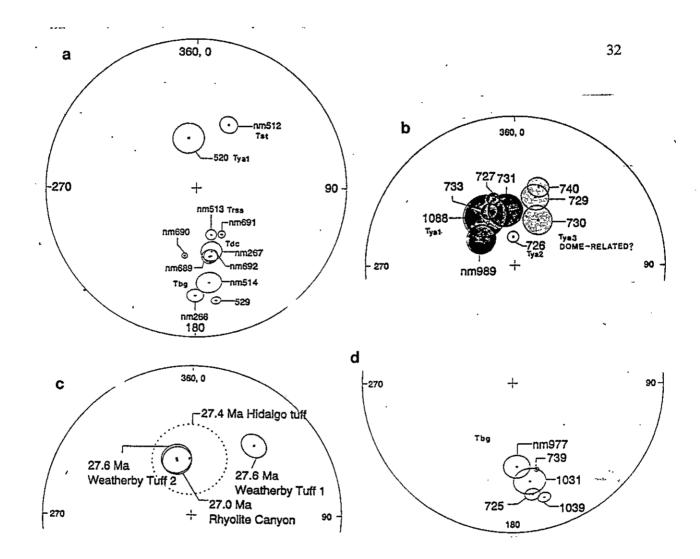

FIGURE 2.4—Stereographic projections of paleomagnetic data from the Steeple Rock area. Sample numbers refer to Table 2.2 and Map 2.

- a) Samples from McIntosh et al. (1990a, b). Trss, Tst (NM513, NM512) ash-flow tuff of Steeple Rock, Tdc (NM267, NM692, NM689) - Davis Canyon Tuff, Tbg (NM514, 529, NM266) - Bloodgood Canyon Tuff, Tya (520) - younger ash-flow tuffs.
- b) Samples of younger ash-flow tuffs from R. M. Appelt, unpublished data. Note that there are three separate tuffs Tya1, Tya2, and Tya3.
- c) Plots of ash-flow tuffs from the Boot Heel field in southern New Mexico (Fig. 2.2). Data from W. C. McIntosh, unpublished data. Note the similarity with younger ashflow tuffs from Steeple Rock (Fig. 2.4b), suggesting possible correlations.
- d). Samples of Bloodgood Canyon Tuff (Tbg) from R. M. Appelt, unpublished data.
- e) Average plots of Bloodgood Canyon Tuff and Davis Canyon Tuff from McIntosh et al. (1990a, b) for comparison.
- f) Plots of samples from unidentified tuffs from the Steeple Rock district, R. M. Appelt, unpublished data. Samples 1100, 1136, 738, 732, and 1038 are probably altered and/or remagnetized Bloodgood Canyon Tuff.

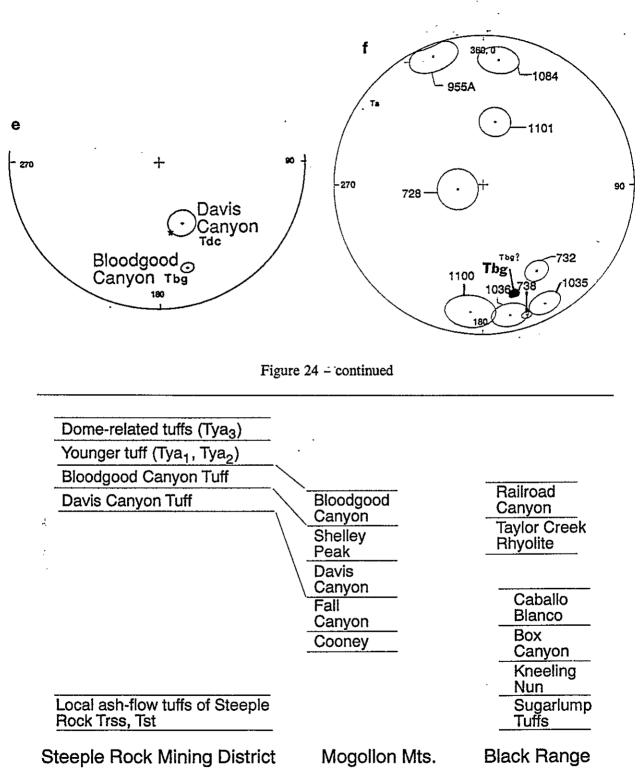

FIGURE 2.5—Stratigraphic correlations of ash-flow tuffs in the Steeple Rock district with Mogollon Mountains and Black Range (Appelt, 1993; McIntosh et al., 1990a, b).

granite exposed in the Burro Mountains and at Redrock (Morrison, 1965; Drewes et al., 1985; McLemore and McKee, 1988a, b). The granite in the Burro Mountains has been dated as 1445-1600 Ma (Stacey and Hedlund, 1983) and a similar age is envisioned for the granite at the Riley Peaks area, which most likely underlies the Summit Mountains at depth.

Cretaceous sedimentary rocks unconformably overlie the Proterozoic granite in the Riley Peaks area. The oldest unit is the Beartooth Quartzite and consists of sandstone and orthoquartzite (Morrison, 1965). The Colorado Formation conformably overlies the Beartooth Quartzite and consists of shallow marine shales, siltstones, sandstones, and minor limestones and conglomerates (Hedlund, 1990b; Morrison, 1965). The Virden Formation (Paleocene and Upper Cretaceous; Elston, 1960; Hedlund, 1990b) also crops out near Riley Peaks and consists of nonmarine fluvial sandstones, conglomerates, and siltstones (Morrison, 1965). The entire exposed Cretaceous-Paleocene section is probably less than 300 m thick in the Riley Peaks area (Morrison, 1965; Hedlund, 1990b).

ņ

Thicker Mesozoic and Paleozoic sections occur in southeastern Arizona which suggests a possibility that pre-Cretaceous rocks may occur beneath the volcanic rocks exposed in the Summit Mountains (Ross, 1973; Hayes, 1978; Hayes and Drewes, 1978; Schumacher, 1978). Up to 1500 m of Paleozoic marine sedimentary rocks (middle Cambrian to late early Permian) occurs in southeastern Arizona (Hayes and Drewes, 1978). Unconformably overlying the Paleozoic rocks, are as much as 12,000 m of Mesozoic sedimentary, volcaniclastic, and volcanic rocks (Hayes and Drewes, 1978). Up to 500 m of Paleozoic and Mesozoic rocks are exposed at Morenci (Moolick and Durek, 1966). However, it is unlikely that the Paleozoic and Mesozoic rocks are more than 500 m thick in the area of study because the Steeple Rock area was probably part of the Burro uplift throughout most of this time (Ross and Ross, 1986; Drewes, 1991). Without extensive subsurface drilling the presence and extent of Paleozoic and Mesozoic rocks beneath the Summit Mountains is only speculative.

2.2.4 Volcanic rocks of Steeple Rock and Mt. Royal

The oldest rocks exposed in the mapped area are the volcanic rocks of Steeple Rock and Mt. Royal in the southern part of the area (Fig. 2.3; Maps 1, 2). These rocks were not studied in thin section for this study because they are not significantly mineralized. Descriptions are based on Hedlund (1990a), Biggerstaff (1974), and field observations. Biggerstaff (1974) calls these rocks the Steeple Rock group, whereas Hedlund (1990a) refers to them as a series of andesites, rhyolites, and tuffs with specific names or designations. They range in age from 34 to 33 Ma (Table 2.1). This sequence of units certainly deserves more study in the future.

2.2.4.1 Andesite of Mt. Royal (Tam) (Hedlund, 1990a)—A sequence of andesite flows forms much of these older rocks. The flows vary in thickness but appear uniform in composition. They are reddish-brown to purplish-gray, highly jointed or fractured, and locally porphyritic. This andesite is difficult to impossible to distinguish from younger andesites of Summit Mountain and Dark Thunder Canyon formations. Total thickness is probably 125-900 m (Biggerstaff, 1974; Hedlund, 1990a).

The andesite is microcrystalline to locally porphyritic, holocrystalline and typically has a trachytic texture. It consists of plagioclase (andesine, Hedlund, 1990a) and biotite with accessory apatite and possibly hornblende. Alteration minerals include sericite, quartz, and hematite (Biggerstaff, 1974). An ⁴⁰Ar/³⁹Ar age of 34.3 Ma is reported by Hedlund (unpubl. report, 1990; see Table 2.1).

2.2.4.2 Ash-flow tuff of Steeple Rock (Tst)—A series of ash-flow tuffs crop out south of Steeple Rock and are interlayered with andesites of Mt. Royal and the older Mud Springs (Hedlund, 1990a), but only one is exposed in the mapped area. It is thin (less than 50 m), gray to orange-gray, poorly to moderately welded, devitrified, lithic-rich and crystal-poor tuff. It is poorly sorted and consists of 1-2% biotite and 1-2% quartz phenocrysts in a fine-grained groundmass of quartz and feldspar. Lithic fragments consist of andesite and andesite porphyry. Paleomagnetic data (Table 2.2) is inconclusive in correlating these tuffs with any

other known major ignimbrites in the area (McIntosh, 1991). This may suggest that these tuffs are locally derived, perhaps from rhyolite doming such as at Steeple Rock.

2.2.4.3 Older sedimentary rocks (Tsed1)—At the base of the rhyolite of Steeple Rock and the rhyodacite of Mt. Royal, a sandstone unit crops out. In both areas, the sandstone units are similar in appearance and composition, and it is unknown if they are the same stratigraphic unit or separate units. The sandstone is light brown to brown to gray, thin to medium bedded, and locally laminated. It is medium to coarse grained, poorly sorted, and consists of lithic fragments, quartz, feldspar, hematite, and a variety of accessory minerals. It is typically less than 5 m thick. These rocks unconformably overlie the andesite of Mt. Royal.

2.2.4.4 Rhyolite of Steeple Rock (Trs) (Hedlund, 1990a)—The rhyolite of Steeple Rock (Steeple Rock flow of Biggerstaff, 1974) is a prominent, massive rhyolite flow or dome that forms much of Mt. Royal and Steeple Rock (Fig. 2.3; Maps 1, 2). It unconformably overlies the older sedimentary rocks (Tsed1) and the andesite of Mt. Royal. It is brecciated toward the top of the unit suggesting a dome-like emplacement. It is light gray to pale red, flow-banded, locally spherulitic, devitrified, and locally, slightly porphyritic lava flow or dome. It ranges in thickness from less than a meter to 200 m. It has been dated as 33.1 ± 1.1 Ma (Table 2.1; Marvin et al., 1988; Hedlund, 1990b). Hedlund (1990a) suggests a vent may occur near the Old Man Hext windmill.

The rhyolite consists of 2% sanidine, 1-2% biotite, and 1-2% quartz phenocrysts in a groundmass of quartz, feldspar, and volcanic glass. Accessory minerals include magnetite, hornblende, and iron oxides. Alteration consists of iron oxides, sericite, and minor silicification. This unit is unconformably overlain by the Summit Mountain formation or the rhyodacite of Mt. Royal (Maps 1, 3).

2.2.4.5 Rhyodacite of Mt. Royal (Trd)—A rhyodacite crops out on the north end of Mt. Royal. Hedlund (1990a) calls this unit the rhyodacite of Carlisle Canyon. This unit is brown-gray to pale-red, foliated, devitrified, and spherulitic rhyodacite dome or intrusive. It is highly fractured and jointed. The joints and fractures do not correspond to foliation; they

may be cooling features. It consists of 25% plagioclase (oligoclase, Hedlund, 1990a), 1% sanidine, 2% quartz, and 3-5% biotite in a fine-grained groundmass of feldspar, volcanic glass, and hornblende or biotite. Accessory minerals include magnetite and apatite. Alteration minerals include chlorite, calcite, quartz, and possibly epidote near the Imperial fault which cuts the unit. This unit has a maximum thickness of 125 m (Hedlund, 1990a) and is unconformably overlain by the Summit Mountain formation.

2.2.5 Summit Mountain formation (Tss)

The Summit Mountain formation (Tss) is the most economically important unit in the Steeple Rock district because it is the predominant host of epithermal mineralization and alteration. Alteration of this unit is extensive and fresh, unaltered outcrops are rare. In addition, this unit is highly faulted and nowhere is there a complete unfaulted section exposed. Age dates of this unit range from 31 to 32 Ma (Table 2.1).

The Summit Mountain formation consists of lava flows, breccias, and volcaniclastic sedimentary rocks. An intrusive andesite also crops out near New Seep windmill. The unit unconformably overlies the rhyodacite of Mt. Royal and the rhyolite of Steeple Rock. It is unconformably overlain by Bloodgood Canyon Tuff, younger ash-flow tuffs, or Dark Thunder Canyon formation.

Total thickness of this unit is uncertain because of faulting. Griggs and Wagner (1966) report a minimum thickness of 457 m. Biggerstaff (1974) reports a minimum thickness of 700 m based on drilling east of Twin Peaks, whereas Hedlund (1990a) reports a possible thickness of 610 m. Drill holes along the East Camp-Summit and Norman King-Billali faults are as much as 518 m deep and remain within the Summit Mountain formation. The Bitter Creek #1 drill hole is 762 m deep and remains in andesite, presumably of the Summit Mountain formation formation, although the bottom of the hole may actually be in older andesites of Mt. Royal or Mud Springs, which are similar in appearance and composition. The thickness of the Summit Mountain formation is unknown, but probably exceeds 760 m in some areas.

This unit was referred to as the purple andesite porphyry by Griggs and Wagner (1966) and Biggerstaff (1974). Hedlund (1990a, b, c, 1993) designated this unit as the dacite (or dacite porphyry) of Summit Mountain.

2.2.5.1 Andesite and dacite lava flows (Tss)—Lava flows within the Summit Mountain formation are predominantly andesites, andesite porphyries, and less common dacites. Quartz is rarely present as a primary mineral, however, visual examination of many flows will show the presence of small "phenocrysts" of quartz (up to 5 mm in diameter). In thin section, these quartz "phenocrysts" are actually infilling of vugs or amygdules. Some flows do contain primary quartz phenocrysts and are true dacites.

The flows vary somewhat in color from purple to gray to red to brown to black. They are typically porphyritic, thin bedded to massive and locally contain small vesicles or amygdules (Fig. 2.6). The flows vary in appearance and composition; this heterogeneity is characteristic of the entire formation and enables it to be differentiated from the older andesite of Mt. Royal and the younger Dark Thunder Canyon formation. The flows also vary in composition (Appendix 11.4) but typically contain as much as 20% (up to 60% locally) phenocrysts of plagioclase (oligoclase to andesine, Hedlund, 1990a, 1993), hornblende, biotite, pyroxene, and magnetite. Accessory minerals include apatite, titanite, zircon, quartz, and perhaps olivine. Alteration is pervasive and discussed elsewhere. Trachytic textures are common. Some flows are aphanitic.

2.2.5.2 Volcaniclastic sedimentary rocks (Tsed)—Numerous outcrops of volcaniclastic sedimentary rocks occur throughout the Summit Mountain formation. Correlation is difficult because of discontinuity, pinchouts, faulting, and lack of distinguishing characteristics. These units vary from volcanic breccias to andesitic-dacitic tuffs to sandstones to siltstones to rare mudstones. Where altered, they are difficult to distinguish from altered rhyolite ash-flow tuffs. In general, these units are variable in color ranging from various shades of purple, red, gray, green, white to brown, are thin- to medium-bedded, locally laminated or crossbedded, poorly sorted, and consist of angular to subangular fragments of

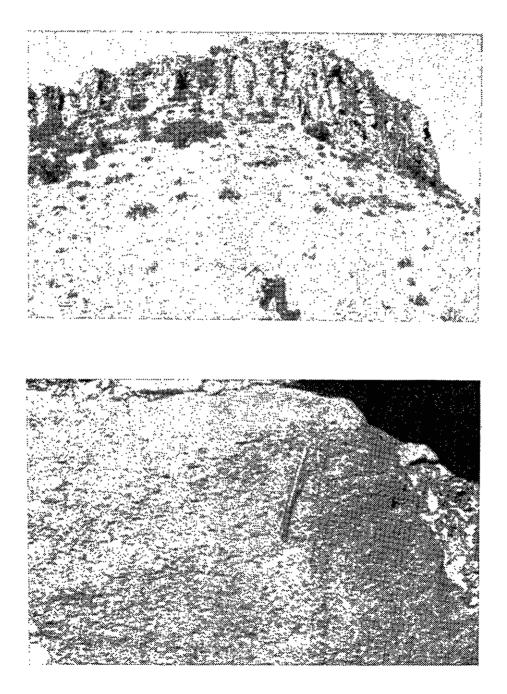

Figure 2.6-View of andesite flow in Summit Mountain formation at Summit Mountain.

lithic fragments of andesite, andesite porphyry, rhyolite, and breccia. Material from silicified veins and breccia zones is absent, indicating deposition prior to epithermal mineralization. Sand and silt size grains consist of lithic fragments, quartz, plagioclase, magnetite and K-feldspar cemented by clay, silica, manganese, or hematite. Tuffs consist of volcanic glass as well as quartz, feldspar, and lithic fragments. Alteration is common and many areas have been intensely altered to clays and other minerals indicative of acid-sulfate alteration (Appendix 11.2). These breccias are poorly sorted, consist of angular fragments in a mudstone matrix, and were probably deposited as mudflows and volcanic lahars. The sandstones and siltstones were deposited as river or stream deposits between periods of lava eruption. They are more common near the top of the Summit Mountain formation and locally occur at depth in the drill holes. The most extensive outcrops of volcaniclastic sediments are at the Carlisle-Center area and east of Telephone Ridge in the Raeburn Hills area (Maps 1, 2; Fig. 2.3). Total thickness rarely exceeds 30 m, however drilling by FMC Gold Co. at Raeburn Hills indicates total thickness of 213 m (E. M. Crist, unpubl. report, October 1988).

2.2.5.3 Intrusive andesite (Tv)—Intrusive andesite intrudes the Summit Mountain andesite flows just east of the New Seep Windmill. This unit is a red to brown, porphyritic plug or dome. Hedlund (1990a) refers to it as porphyritic dacite. Near the top of the unit are iseveral outcrops of volcanic breccia. The contacts with the andesite lava flows are not well exposed, but appear irregular and intrusive. Fine-grained margins occur locally in the intrusive andesite near contacts with andesite flows. It consists of 35% plagioclase (andesine, Hedlund, 1990a), 5-10% hornblende, and 2-5% biotite in a fine-grained spherulitic groundmass of feldspar, volcanic glass, and hornblende or biotite.

2.2.5.4 Altered tuff, sediments and andesite undifferentiated (Tas)—Near the top of the Summit Mountain formation are local zones of intensely acid-sulfate altered rocks, up to 500 m thick locally. These rocks are silicified and altered to clay. They are typically white to maroon to variegated gray, purple, brown, and red. The original lithology of these rocks is obscured by the intense alteration, but they appear to be andesites, sedimentary rocks, and

ash-flow tuffs on the basis of stratigraphic position and relict textures and mineralogy. These rocks are described in more detail in section 5.3.

2.2.6 Davis Canyon Tuff (Tdc?)

A tuff crops out in the southern portion of the study area, east of Steeple Rock (Maps 1, 2) and is tentatively correlated with the Davis Canyon Tuff (Tdc?) on the basis of stratigraphic position. The tuff is light gray to tan to white, locally welded, devitrified, ash-flow tuff that is crystal poor, but characterized by coarse stringy white to gray to brown pumice, several millimeters long, which is characteristic of the Davis Canyon Tuff (Ratté et al., 1984; Hedlund, 1990a). The tuff contains less than 15% phenocrysts (up to 3 mm long) of sanidine, plagioclase, quartz, and biotite with accessory titanite. Lithic fragments of andesite are common (up to several centimeters in diameter; #649, NM960, Appendix 11.2). The tuff is poorly sorted and consists of angular to subangular, broken crystals. It is unconformably overlain by the Bloodgood Canyon Tuff and it unconformably overlies volcaniclastic sandstones or andesites of the Summit Mountain formation. Locally the tuff consists of large boulders of andesite, rhyolite, and tuff (1 m diameter).

The Davis Canyon Tuff is a distinctive outflow sheet derived from the Bursum caldera in the Mogollon Mountains, northeast of the study area (Figs. 2.2, 2.5; Ratté et al., 1984). The Steeple Rock district is the southwestern extent of the Davis Canyon Tuff (McIntosh et al., 1990b). The age of the tuff has been determined by 40 Ar/ 39 Ar dating as 29.01±0.11 Ma (McIntosh et al., 1990a, b). The tuff has a distinctive paleomagnetic character which enables differentiation from other tuffs in the area (Table 2.2, Fig. 2.4).

2.2.7 Bloodgood Canyon Tuff (Tbg)

The Bloodgood Canyon Tuff (Tbg) crops out throughout the mapped area (Fig. 2.3; Maps 1, 2). The tuff is a light-gray to white, typically welded, devitrified ash-flow tuff that is crystal rich and is characterized by round "eyes" of sanidine and bipyramidal quartz (Ratté et al., 1984; Hedlund, 1990a, b, c, 1993). The tuff is poorly sorted, angular to subangular and consists of 10-20% phenocrysts, up to 3-5 mm across, of sanidine, quartz, and accessory titanite, biotite, hornblende, and iron oxides (Appendix 11.2). This unit was mapped as Noah Mesa tuff by Wahl (1980), however not all of Wahl's Noah Mesa tuff is Bloodgood Canyon Tuff. Hedlund (1990a, b, c, 1993) also mapped some outcrops of ash-flow tuff as Bloodgood Canyon Tuff which are actually younger ash-flow tuffs. The Bloodgood is easily confused with the younger ash-flow tuffs, especially where weathered or altered and locally only paleomagnetic analysis can distinguish between the tuffs. The Bloodgood Canyon Tuff has a distinctive reversed-polarity paleomagnetic signature that distinguishes it from the younger ash-flow tuffs which have normal polarity (Table 2.2, Fig. 2.4). The Bloodgood Canyon Tuff also contains variable amounts of volcanic lithic fragments, typically andesite or basaltic andesite.

In the Steeple Rock district, the Bloodgood Canyon Tuff unconformably overlies either volcaniclastic sedimentary rocks, andesites and dacites of Summit Mountain formation or the Davis Canyon Tuff (Fig. 2.3; Maps 1, 2). The Bloodgood Canyon Tuff is unconformably overlain by the basaltic andesites of the Dark Thunder Canyon formation. In the Steeple Rock district the Bloodgood Canyon Tuff ranges in thickness from less than a meter to approximately 75 m locally.

The Bloodgood Canyon Tuff is one of the most widespread ash-flow tuffs in the Mogollon-Datil volcanic field. It extends from its source, the Bursum caldera in the Mogollon Mountains (Fig. 2.5), northward to Aragon and as far south as a few kilometers south of Steeple Rock. It extends as far west as Clifton and as far east as Beaverhead (McIntosh et al., 1990a, b). The age of the unit has been determined by 40 Ar/ 39 Ar dating as 28.05±0.01 Ma (McIntosh et al., 1990a, b).

2.2.8 Dark Thunder Canyon formation (Tbd)

1.1

The Dark Thunder Canyon formation (Tbd) consists of multiple gray to brown to

purple to red porphyritic amygdaloidal andesitic to basaltic andesite lava flows with interbedded younger ash-flow tuffs and volcaniclastic sandstones. Griggs and Wagner (1966) called this unit the amygdaloidal andesitic basalt whereas Biggerstaff (1974) called it andesitic basalt. Hedlund (1990a, c; 1993) called the unit basaltic and andesitic rocks of Dark Thunder Canyon. Individual lava flows are typically uniform in composition (Fig. 2.7) and range up to 15 m thick. The unit is characterized by abundant vesicles or amygdules, typically filled with quartz, calcite, and thomsonite (Biggerstaff, 1974). The unit is unconformably overlain by lava flows of Crookson Peak and it unconformably overlies younger ash-flow tuffs, Bloodgood Canyon Tuff or Summit Mountain formation. The younger ash-flow tuffs (Tya, Ta) are also interbedded with the lavas near the base of the unit.

In thin section, the lavas are fine- to medium-grained, hypocrystalline (original glass content probably as much as 15%), trachytic, porphyritic, and locally seriate. The flows typically consist of plagioclase (andesine; Hedlund, 1990a, c, 1993), magnetite, hornblende, pyroxene, and biotite. Alteration minerals include chlorite, calcite, clay, quartz, hematite, and leucoxene. Local accessory minerals include apatite, zircon, and titanite. Olivine was not seen in this study but has been reported by previous workers (Biggerstaff, 1976; Griggs and Wagner, 1966).

The Dark Thunder Canyon formation is as much as 800 m thick (Hedlund, 1990a, c, 1993). Near the base of the unit, the lava flows are interbedded with younger ash-flow tuffs (Ta or Tya) or poorly sorted, poorly rounded, volcaniclastic sandstones, conglomerates, and locally, volcanic breccias (Tsed). These rocks were probably deposited between periods of lava eruption.

2.2.9 Younger ash-flow tuffs

A series of outcrops of ash-flow tuffs (Tya, Ta) occur at or near the base of the Dark Thunder Canyon formation (Maps 1, 2). These tuffs can be distinguished from one another and from the Bloodgood Canyon Tuff primarily by paleomagnetic analyses (Table 2.2). These tuffs typically have a normal paleomagnetic polarity as opposed to the reverse paleomagnetic polarity characteristic of the Bloodgood Canyon Tuff. The younger ash-flow tuffs have different declinations which suggest two or three closely erupted ash-flow tuffs were emplaced in the Steeple Rock area (Fig. 2.5). Where paleomagnetic or other data are lacking, the tuffs are designated as undifferentiated on Maps 1 and 2 (Ta).

D. C. Hedlund (pers. comm. June 1990) recognized the difficulty in correlating these tuffs because of their similarity in appearance and composition, especially where altered. They vary in color from various shades of yellow, gray, brown to white. Some are lithic rich and crystal poor and locally vary within both a vertical section and laterally. Thicknesses vary from 0 to 30 m. Welding varies from nonwelded to welded.

The tuffs are lighter in color than the andesites and contain essential quartz, sanidine, and biotite phenocrysts in a groundmass of pumice, quartz, and feldspar. Lithic fragments, typically andesite and andesite porphyry, are common and range in size from microscopic to 0.8 m in diameter.

The tuffs are interbedded within the lower portion of the andesite of Dark Thunder Canyon formation (Fig. 2.8), although locally they may also lie unconformably on Summit Mountain formation. In places, they commonly form ridges and hill tops.

2.2.10 Lava flows of Crookson Peak (Tlc)

The lava flows of Crookson Peak (Tlc) consist of predominantly red-brown to grayishred dacitic to andesitic lava flows that lie unconformably on the Dark Thunder Canyon formtaion. These lava flows form prominent southwest-facing cliffs along the eastern border of the mapped area from Apache Box (north of the mapped area) southward to Crookson Peak and Juniper Peak (Fig. 2.3; Maps 1, 2). This is the same unit as the brown andesite porphyry unit of Biggerstaff (1974) and Griggs and Wagner (1966). Maximum thickness is approximately 460 m (Hedlund, 1990b, c). No thin sections of this unit were examined for

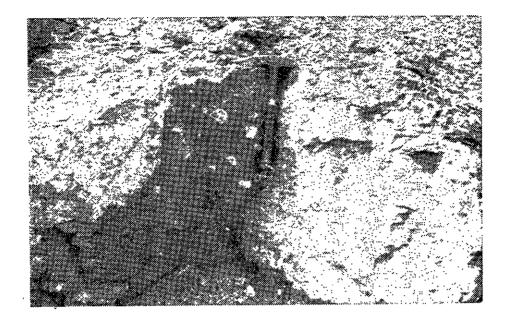

Figure 2.7—View of andesite of Dark Thunder Canyon, near Alabama Ridge.

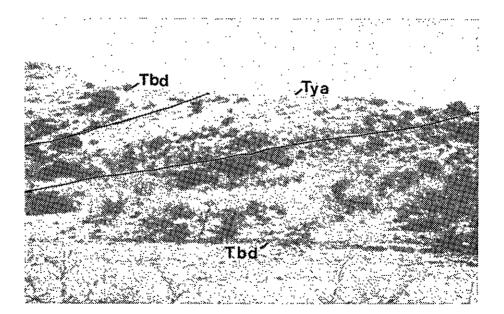

Figure 2.8—View of younger ash-flow tuff (Tya) interbedded within andesite of Dark Thunder Canyon (Tbd). Located in Carlisle Canyon, south of Mt. Royal mine (#726, Map 2). this study. However, Hedlund (1990a) describes the unit as containing 10-20% oligoclase andesine (An_{28-33}) phenocrysts, locally glomeroporphyrtic, in a felted to pilotaxitic groundmass with disseminated iron oxides and clinopyroxene granules. Griggs and Wagner (1966) also report the presence of augite, magnetite, biotite, and rare quartz and K-feldspar. Less altered portions of the lava flows also contain volcanic glass.

2.2.11 Rhyodacite of Willow Creek (Twd)

The rhyodacite of Willow Creek (Twd) crops out north of the Foothills fault in the northwestern portion of the mapped area (Fig. 2.3; Maps 1, 2). It corresponds to the rhyodacite porphyry of Willow Creek of Hedlund (1990c). It is light brown to gray to gray-red, porphyritic to glomeroporphyritic, foliated rhyodacite flow and lies unconformably on the Summit Mountain formation. This unit grades into a rhyolite flow or dome. Thin sections of this unit were not examined for this study, however, Hedlund (1990c) describes it as a porphyritic flow with a pilotaxitic groundmass. It consists of 5% quartz, 2-3% sanidine, 10% plagioclase (andesine; Hedlund, 1990c) phenocrysts in a groundmass of volcanic glass, feldspar and hornblende or biotite. Accessory minerals include biotite, hornblende, and possibly magnetite. Alteration minerals include iron oxides, sericite, calcite, chlorite, and quartz.

2.2.12 Rhyolite flows and/or domes (Twr)

Rhyolite flows and/or domes (Twr) occur in four areas west of Saddleback Mountain in the northwestern portion of the map area (Maps 1, 2). These units are pink to red to white to gray, foliated to flow-banded, aphanitic to slightly porphyritic rhyolite flows or domes. Locally, they are associated with ash-flow tuffs and/or small zones of pyroclastic fall deposits. Brecciation is locally common. The complex due west of Saddleback Mountain also is associated with black, discontinuous bands of vitrophyre that contain small phenocrysts of sanidine. A sample of the vitrophyre has an ${}^{40}\text{Ar}/{}^{39}\text{Ar}$ date of 25.3 \pm 0.10 Ma (W. C.

46

McIntosh and R. Appelt, unpublished data, Aug. 1993). Local ash-flow tuffs may also be derived from these domes and rhyolite plugs.

The rhyolites consist of quartz, plagioclase, sanidine, biotite, and volcanic glass. The groundmass is spherulitic to cryptocrystalline (Appendix 11.2). Alteration minerals include iron oxides and sericite and silicification is common locally. Thicknesses probably do not exceed 250 m except at the vents. They are younger than the Summit Mountain and Dark Thunder Canyon formations and may be erupted from a similar source at depth.

2.2.13 Intrusive rocks

Numerous dikes, plugs, and domes occur throughout the study area (Maps 1, 2). Compositions include diabase dikes, quartz monzonite dikes, and rhyolite and rhyodacite dikes, which also include the Apache Box complex, Vanderbilt Peak complex, Piñon Mountains rhyolite, and Twin Peaks rhyolite. Most of the intrusive rocks appear to be fault controlled. Although their age is uncertain, most are younger than 27 Ma because they intrude rocks of that age. Many of the intrusives in the Steeple Rock area have not been dated because they are too silicified and altered. However, a rhyolite dome and two rhyolite dikes in the Steeple Rock district and a number of rhyolite intrusives elsewhere in the vicinity of the study area have been dated (Table 2.1) and these age dates suggest that multiple periods of rhyolitic intrusion occurred between 17 and 28 Ma (Hells Hole; Ratté and Brooks, 1983). The intrusive rocks in the Steeple Rock area possibly represent similar successive periods of emplacement. Some rhyolite dikes intrude older rhyolites. Brecciation is common. Some rhyolites are cut by faults and younger rhyolites, whereas other rhyolites are emplaced along faults. The age of the Steeple Rock rhyolites is probably between 17-28 Ma.

2.2.13.1 Diabase dikes (Td)—Small dikes of altered diabase are found sporadically throughout the Steeple Rock area; some of the larger dikes are shown on Maps 1 and 2. One or more dikes occur in the vicinity of Twin Peaks (Biggerstaff, 1974), near Summit Peak, near the Rattlesnake mines (west of Charlie Hill), north of the Carlisle mine (Powers, 1976),

and at East Camp. Powers (1976) called these microdiorite porphyry, Biggerstaff (1974) calls these basalt or microdiabase, and Griggs and Wagner (1966) called these diorite or diorite porphyry. These dikes are green to gray-green, less than a meter wide, and characterized by a trachytic texture of white plagioclase needles in a fine-grained, chloritized matrix. In thinsection, the diabase is fine- to medium-grained, with a seriate, holocrystalline, and porphyritic to glomeroporphyritic texture. It consists of essential plagioclase and hornblende, pyroxene, or biotite (now completely altered to chlorite) and accessory magnetite, biotite and titanite. Alteration minerals include chlorite, sericite, quartz, hematite, leucoxene, pyrite, epidote, and adularia (#169,187, Appendix 11.4).

2.2.13.2 Quartz monzonite dike (Tq)—A dike of quartz monzonite which is up to 30 m wide and almost 8 km long cuts the rhyolite of Steeple Rock in the southern portion of the mapped area (Fig. 2.3; Maps 1, 2; Hedlund, 1990a). Hedlund (1990a) reports an age date of 21.4 \pm 1.6 Ma from this dike. Powers (1976) refers to the dike as granite porphyry whereas Hedlund (1990a) called it quartz monzonite porphyry. According to the classification of LeMaitre (1989) the dike is a quartz monzonite.

The dike is medium- to coarse-grained, porphyritic to glomerophyritic, and holocrystalline. It is sinuous and pinches and swells along strike. It consists of plagioclase (oligoclase; Hedlund, 1990a), K-feldspar, quartz, and accessory biotite, magnetite, titanite, hornblende, and zircon (#651, Appendix 11.4). Alteration minerals (probably originally hornblende, biotite, titanite, and feldspar) consist of sericite and hematite.

2.2.13.3 Rhyolite and rhyodacite dikes (Tr, Trp)—Numerous rhyolite and rhyodacite dikes cut the volcanic rocks of the Steeple Rock area (Fig. 2.3; Maps 1, 2). Hedlund (1990b) reports a fission track age on zircon from a rhyolite dike as 21 Ma, however the exact sample location is unknown. Wahl (1983) also reports an age from a rhyolite dike of 18 Ma, but the location is unknown. R. Applet (unpublished data, 1993) reports an age determination from a rhyolite dome west of Saddle Back Mountain as 25.3 ± 0.10 Ma (Table 2.1). Many are undoubtedly related to intrusive plugs and necks and some may be indicative of larger intrusions at depth. Many occur in discrete belts or swarms that commonly trend northwest and northeast. Most previous workers have identified them as rhyolite or rhyodacite composition. However, Powers (1976) also refers to them as intrusive breccia, banded rhyolite, and granite porphyry. Terminology defined by LeMaitre (1989) is used here.

The intrusive rocks range in color, depending on alteration and composition, from white to gray to pink to red to purplish gray. The dikes range in size from less than 6 m wide and up to several 100s of meters long. They are sinuous and pinch and swell along strike. Textures are variable. They are aphanitic or microcrystalline to porphyritic to glomeroporphyritic (Fig. 2.9). Near vertical flow-banding is common. Spherulitic textures are locally preserved. Autobrecciation is also locally common. The rhyolites are typically phenocryst poor (less than 15%) and consist of quartz, k-feldspar, and accessory biotite, hornblende, titanite, and zircon. Alteration is common, especially silicification (Appendix 11.4).

2.2.13.4 Apache Box rhyolite complex—Although the Apache Box rhyolite complex lies just north of the mapped area, it is described here because it is similar in age and appearance to other rhyolite intrusives within the mapped area. This complex consists of a series of rhyolite plugs and dikes, some of which are vertically flow-banded, that have intruded Dark Thunder Canyon formation and the lava flows of Crookson Peak (Hedlund, 1990c; Ratté and Hedlund, 1981).

The rhyolite is pink to red to light brown-gray, fine-grained, crystal-poor to porphyritic to glomerophyritic and holocrystalline. It consists of plagioclase (oligoclase; Ratté and Hedlund, 1981), sanidine, quartz and accessory biotite, zircon, and magnetite (#1048, Appendix 11.4). Alteration minerals include sericite and hematite and silicification is common.

2.2.13.5 Vanderbilt Peak rhyolite complex (Tr)—Rhyolite plugs intrude the Dark Thunder Canyon formation on the southern end of Vanderbilt Peak and south of the peak (Fig. 2.3; Maps 1, 2). Numerous rhyolite dikes extend southward from the peak and also

.

44. 4 47

. .

Figure 2.9-Flow-banded rhyolite dike, Alabama Ridge.

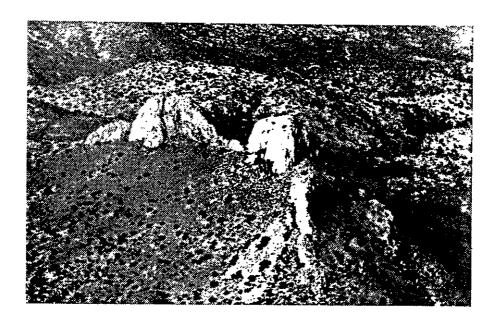

Figure 2.10—View of Twin Peaks rhyolite (northern part of map area). View from the air looking southwest.

**.> --4'- form dike swarms around Vanderbilt Peak. Most of the plugs and dikes appear to be fault controlled, although some have been offset by younger faulting. The dikes continue southward, where they become part of the Piñon Mountains rhyolite plug. The dikes and plugs are similar in appearance, mineralogy, and chemistry and probably were emplaced at the same time from the same source (Biggerstaff, 1974). Ash-flow tuffs and volcanic breccia deposits surround some of the plugs, suggesting the plug breached the surface and produced pyroclastic deposits.

The rhyolite is fine- to medium-grained, flow-banded, and varies in color from various shades of red, brown to gray. It is crystal-poor to porphyritic to glomerophyritic and holocrystalline. The rhyolite consists of quartz, sanidine and accessory biotite, hornblende, zircon, and magnetite. Accessory minerals include sericite, hematite, and silicification is common (Appendix 11.2).

2.2.13.6 Piñon Mountains rhyolite (Tr)—A large rhyolite plug forms much of the Piñon Mountains. This rhyolite intrudes Summit Mountain formation and Bloodgood Canyon Tuff. Paleomagnetic data confirms this tuff as Bloodgood Canyon Tuff (#1039, Table 2.2); however, it is possible that some outcrops of tuff may actually be related to emplacement of the Piñon Mountains rhyolite. Rhyolite dikes extend northwest and southeast which are probably related to this intrusion.

This rhyolite is fine-grained, locally flow-banded, and varies in color from various shades of red to gray. It is typically crystal-poor, although locally it is porphyritic. It is holocrystalline and consists of quartz, plagioclase, sanidine, and accessory biotite, magnetite, zircon, and possibly hornblende. This rhyolite is less altered than at Vanderbilt Peak, however locally it is altered to hematite and sericite and silicification is also locally common (Appendix 11.4).

2.2.13.7 Twin Peaks rhyolite (Tr)—The Twin Peaks rhyolite dike or plug forms the prominent Twin Peaks (Fig. 2.10). The intrusive is gray to red to orange, fine-grained, porphyritic, and holocrystalline to hypocrystalline (less than 5% glass; Biggerstaff, 1974). It

is up to 100 m wide and 600 m long and forms prominent cliffs. The rhyolite consists of K-feldspar, biotite, magnetite, and titanite (#1028, Appendix 11.4). Biggerstaff (1974) also reports primary hornblende. Alteration minerals consist of sericite, hematite, leucoxene, kaolinite, pyrite and malachite. Some quartz is probably also hydrothermal or secondary. Nearby dikes may also be genetically related to the Twin Peaks rhyolite.

2.2.14 Quaternary rocks

It is beyond the scope of this report to examine the Quaternary units in any detail; however, four units are designated on the geologic maps (Maps 1, 2; Hedlund, 1990a, b, 1993). The oldest unit, the Gila Group, is Pleistocene to Miocene in age (QTg; Maps 1, 2). This unit consists of poorly bedded, moderately indurated, poorly-sorted fanglomerate with some sand, silt and gravel deposits. This unit is as much as 300 m thick (Hedlund, 1993). The next unit (Qaf) consists of alluvial-fan deposits which contain floodplain deposits of unconsolidated, poorly sorted, subangular to angular fragments of Tertiary volcanic rocks. Locally these fan deposits are as thick as 85 m (Hedlund, 1990a, b, c). The youngest unit (Qal), alluvial gravels, consists of unconsolidated, poorly-sorted gravel, sand, and silt and also contains fragments, including boulders, of Tertiary volcanic rocks. This unit occurs within arroyos and streams and is probably less than 3-4 m thick.

A sinter or spring deposit (Qs), presumably of Quaternary age, crops out in Bitter Creek (sec. 20, T16S, R21W). The material is soft, friable, unconsolidated, white to tan, and varies in texture from spongy to poorly indurated. It consists of gypsum, silica (amorphous), and calcareous clay (SINTER, Appendix 11.3). The maximum thickness is probably less than 8 m.

2.3 Structural Geology

2.3.1 Regional

The regional structural evolution of the southwestern United States and northern

Mexico has been dominated by a succession of dynamic and sometimes rapidly changing plate tectonic settings from the Proterozoic to the Recent (Coney, 1978; Karlstrom and Bowring, 1988; Karlstrom et al., 1990). This prolonged history of complex continental tectonics can be divided into eight phases: (1) Mazatzal orogeny, 1650-1600 Ma (Karlstrom and Bowring, 1988; Karlstrom et al., 1990), (2) Late Proterozoic granitic plutonism, 1450-1400 Ma (Karlstrom and Bowring, 1988; Stacey and Hedlund, 1983), (3) Paleozoic period of basin formation and uplift (Florida uplift, Pedregosa Basin, southern extension of Ancestral Rocky Mountains, Ross and Ross, 1986), (4) late Triassic to late Jurassic magmatic arc activity in western Arizona, northern Mexico, and California (which did not extend into New Mexico; Drewes, 1991), (5) Cretaceous back-arc, shallow marine deposition, (6) Laramide compressional deformation and magmatic arc volcanism and plutonism (Late Cretaceous to early Tertiary), (7) mid-Tertiary calc-alkaline volcanism to bimodal volcanism with caldera formation, and (8) late Tertiary-Quaternary Basin and Range extensional deformation (Coney, 1978). Each of these tectonic periods left remnant structural trends that were either reactivated or crosscut by younger tectonic events and together have resulted in a structurally complex, relatively thin, brittle crust; a perfect setting for epithermal deposits.

Although each tectonic event had lasting effects, the most important tectonic events affecting the Steeple Rock area are the more recent events. Since Late Cretaceous times, southwestern New Mexico, and most of the southwestern United States and northern Mexico, have undergone episodic tectonic activity. This tectonic activity was related to complex motions of lithospheric plates off the coast of California. Laramide compressional deformation from Late Cretaceous to early Tertiary formed a series of north- to northwest-trending uplifts and broad shallow basins (Seager et al., 1986; Drewes, 1991). This Laramide compressional event resulted from the rapid subduction of the Farallon plate beneath the North American plate (Coney and Reynolds, 1977; Keith, 1978; Dickinson, 1981). Most of the Laramide event in New Mexico was amagmatic, however, arc magmatism migrated eastward as subduction continued, producing several Laramide intrusions in eastern Arizona and southwestern New Mexico. The copper porphyry intrusives at Safford, Morenci, Santa Rita, and Tyrone are products of this event (Figs. 1.1, 2.2; Coney and Reynolds, 1977; Titley, 1982; Davies, 1989). Although rocks of Laramide age are not exposed in the mapped area of the Steeple Rock district, Laramide faults have exposed portions of the Proterozoic and Paleozoic crust south of Steeple Rock at Riley Peaks (Hedlund, 1990a; Drewes et al., 1985).

Starting at 50-40 Ma, extensive intermediate to silicic calc-alkaline volcanism and associated plutonism occurred throughout southwestern New Mexico and adjacent Mexico and resulted in major andesitic volcanic centers and numerous calderas (Table 2.3). Then at about 40-50 Ma, several large volcanic fields developed in the area from Colorado southward into Mexico and Texas (Table 2.3, Fig. 2.2) and temporally coincided with the change in tectonic style from Laramide compressional to Tertiary extensional deformation. This change in tectonic style also coincided with a change in magmatism from calc-alkaline to bimodal compositions.

The tectonic style during this period is controversial and varies from place to place. Individual rhyolite ash-flow sheets (ignimbrites) spread across thousands of square kilometers in southern New Mexico and Arizona (Ratté et al., 1984; Ratté and Gaskill, 1975; Morgan et al., 1986; Drewes et al., 1985; McIntosh et al., 1990a, b, 1992a) and suggest to some investigators that neither active extension nor active compression was dominant. Many of the dominant of the steeple Rock district were emplaced during this period.

.....

Some geologists believe that mid-Tertiary arc magmatism was accompanied by backarc or arc extension during this time (Elston, 1984; Engebretson et al., 1984). Cather (1990) suggests incipient extension in central New Mexico began about 36 Ma. Others believe that Laramide compression continued until about 32 Ma (Henry and Price, 1986; Price and Henry, 1984). It is apparent from the literature that the transition between Laramide compressional and mid-Tertiary extensional deformation varied from place to place and is difficult to date in most areas.

Thus the orientation of the stress fields and resultant structural styles of deformation

Field Type of Volcanism Age Area 25,000 sq km San Juan field intermediate composition 35-26 Ma then shifts to bimodal at 26 Ma Jemez-Questa Questa-bimodal, 26-15 Ma 13-0.13 Ma peralkaline; Vallesbimodal, subalkaline Mogollon-Datil calc-alkaline to bimodal 40-20 Ma 40,000 sq km volcanism with calderas -Trans-Pecos Texas alkaline volcanism with 48-17 Ma 4,000 sq km calderas, change from bimodal to alkalineintermediate at 28 Ma Sierra Madrecalc-alkaline to intermediate 450,000 sq km 100-45 Ma, Occidental volcanism with some mafic 34-23 Ma flows (bimodal) associated with calderas

during this transition period are uncertain. However, by 30-25 Ma, the changing patterns of sedimentation, magmatism, and deformation throughout New Mexico and eastern Arizona indicate that extensional deformation was the dominant tectonic style. The prominent structural features resulting from this extensional tectonic period were half-grabens bounded by near-surface high-angle normal faults which produced the valleys and mountains so characteristic of the Basin and Range province. These high-angle faults may flatten at depth forming listric faults. Most of the rocks in the Steeple Rock mining district were erupted and emplaced at the end of this transition period, 34 to 17 Ma.

Many of the intrusives and volcanic centers in southwestern United States and Mexico

appear to be controlled by regional lineaments (Mayo, 1958; Wertz, 1970a, b; Lowell, 1974; Chapin et al., 1978). For the purposes of this study, a lineament is defined as a broad, linear zone of topographic, structural, and magmatic features, including faults, alignment of volcanic and plutonic centers, uplifts and basins (Bates and Jackson, 1980; Heyl, 1983). Current theories on the evolution of continental lineaments suggest that they are deep-seated, reactivated zones of crustal weakness that have been active sporadically since Proterozoic times (Heyl, 1983; Favorstiaya and Vinogradov, 1991).

.

. عدر

• •

J

÷

At least three lineaments occur in the vicinity of the Steeple Rock area (Fig. 2.2). The Texas lineament extends from Trans-Pecos Texas west-northwestward into southeastern Arizona where it probably joins the Arizona transitional zone (Muehlberger, 1980; Wertz, 1970a, b). It is a prominent 80-150 km wide zone that is defined by basins, ranges, and structural features (Lowell, 1974; Wertz, 1970a, b; Turner, 1962; Schmitt, 1966; Drewes, 1991). Dip-slip (normal, steep reverse or thrust) movements are common throughout this zone and locally strike-slip movement has been documented (Turner, 1962; Wertz, 1970a, b; Muehlberger, 1980). The Steeple Rock mining district lies on the northeastern edge of the Texas lineament.

North of the Steeple Rock area is the prominent northeast-trending Morenci lineament (Fig. 2.2). The Morenci lineament can be traced from Safford, Arizona, northeast to Reserve, New Mexico, and includes the Safford and Morenci porphyry copper deposits. The epithermal silver-gold deposits of the Mogollon district lie on the southern edge of the lineament (Lowell, 1974; Chapin et al., 1978). It also includes the Morenci uplift of Cather and Johnson (1986).

A third potential, but not as well accepted, lineament is positioned south of the Steeple Rock district and is known as the New Mexico mineral belt (Lowell, 1974) or the Santa Rita lineament (Chapin et al., 1978). This lineament extends from Cananea, Sonora, Mexico, northeastward to Santa Rita, New Mexico, and includes the Cananea, Bisbee, Santa Rita, and Tyrone porphyry copper deposits and numerous smaller epithermal districts (Lowell, 1974). It may continue to the northeast through the Kingston and Hillsboro districts in Sierra County, New Mexico (Fig. 1.1; Rose and Baltosser, 1966). This lineament is defined by Laramide intrusives and northeast-trending faults (Rose and Baltosser, 1966).

2.3.2 Local structure

ş

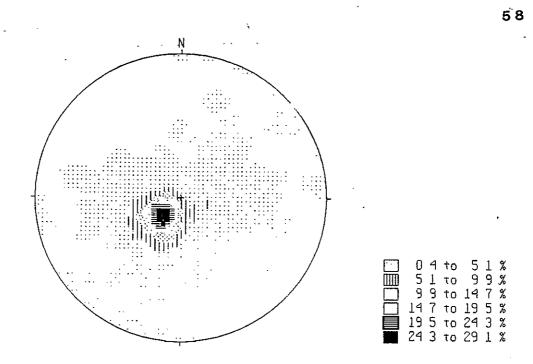

14

Faulting and tilting of the volcanic rocks in the Steeple Rock district produced a series of half-grabens and horsts (Map 3) with a district-wide, regional northwest strike of foliation and bedding planes that dip northeast (10-35°; Fig. 2.11). Foliation, for the purposes of this report, is defined as flow foliation formed by flattening of vesicles or pumice fragments and alignment of phenocrysts. Rhyolite dikes, plugs, and domes were emplaced along some of the faults and then subsequently cut by other faults (Table 2.4). Overall, orientations of rhyolite dikes exhibit a random pattern (Fig. 2.12).

Most faults in the Steeple Rock district are high-angle and well exposed because they are filled with quartz veins and/or silicified, brecciated country rock. The faults can be classified by orientation as (1) northwest-trending faults, (2) north-trending faults, (3) west-northwest-trending faults and shear zones, and (4) northeast-trending faults (Fig. 2.13, Table 2.4). Relative ages of these faults are difficult to interpret because of conflicting field relationships and multiple periods of movement. The term "shear zone" is used in this report to describe a zone of parallel to subparallel anastomosing faults or brittlely shattered or pulverized rock (Marshak and Mitra, 1988). All faults and shear zones in the Steeple Rock district are indicative of brittle deformation; no ductile or brittle-ductile shear zones are recognized in this area.

2.3.3 Northwest-trending faults

The northwest-trending faults are the most prominent and most numerous structural features in the Steeple Rock area (Map 1, Figs. 2.3, 2.13, 2.14). This same northwest trend is observed in both the aeromagnetic and Bouguer gravity data (Wynn, 1981; Klein, 1987), suggesting that deep-seated, regional northwest-trending structural features exist. This

٤,

northwest trend subparallels the west-northwest-trending Texas lineament of Wertz (1970a, b), Chapin et al. (1978) and others. Some of these faults may be a continuation of similar trending faults in the Burro Mountains (Drewes et al., 1985). The Laramide Burro uplift also has a similar northwest trend (Mack and Clemons, 1988; Drewes, 1991). Some of the rhyolite dikes and plugs also have a similar northwest trend, especially south of the Carlisle fault (Maps 1, 2; Fig. 2.12). Some rhyolite intrusives follow discrete fault zones; whereas others occur along northwest-trending fractures or joints. The quartz monzonite dike cutting Steeple Rock also has a northwest trend (Fig. 2.3; Maps 1, 2).

Most of the northwest-trending faults are characterized by quartz veins, silicified wall rock, and/or rhyolite dikes that form prominent outcrops. These faults rarely follow arroyos or current drainage features, although some arroyos will follow northwest-trending faults for short distances. The age and displacements along these faults vary and are the subject of controversy.

South of the Carlisle fault (Fig. 2.3; Maps 1,2), the northwest-trending faults dip to the southwest 55-80° and are downthrown to the southwest. However, the major northwesttrending faults north and east of the Carlisle fault are steeply dipping (>80°) to vertical and are typically downthrown to the northeast (Griggs and Wagner, 1966). Some faults also show reverse movement (Bluebell and East Camp-Summit faults). Displacements also vary along strike of many faults. Faults will be discussed from northeast to southwest.

2.3.3.1 Blue Bell fault—The Blue Bell (Bluebird) fault lies northeast of and subparallel to the East Camp fault. The strike ranges from N50 to 60°W, although local variations are common. The fault consists of either massive quartz veins, quartz-calcite veins or silicified, closely fractured host rock and is up to 8 m wide. South of the Raeburn Hills area, the fault dips steeply to the northeast and is downthrown to the northeast. South of the Blue Bell shaft, the fault splits into two segments (Maps 1, 2; Griggs and Wagner, 1966), which die out southeast of the mapped area (Drewes et al., 1985). The southwestern segment is northwest-trending (N45°W) and offsets a younger ash-flow tuff. The northeastern segment

strikes N65-80°W and is roughly aligned with the Carlisle fault. However, the eastern segment is downthrown to the northeast unlike the Carlisle fault which is downthrown to the south.

÷

North of the Raeburn Hills area, the Blue Bell fault dips to the southwest, but is downthrown to the northeast. The Blue Bell fault splits into a 150-m wide zone consisting of a series of multiple, bifurcating subparallel quartz veins. Some of the thin (<1 m wide) quartz veins intersect the East Camp-Summit fault near the Summit and Bank mines. This zone is probably the continuation of the Blue Bell fault which continues trending northwest, although poorly exposed northwest of Juniper Peak. This zone finally intersects the Norman King-Billali fault near the Mohawk mine. The total length of the Blue Bell fault is approximately 13 km.

Displacement along and age of the Blue Bell fault zone are uncertain. It is unlikely that more than 60 m of displacement have occurred along the Blue Bell fault, based on displacement of the Bloodgood Canyon Tuff (Map 3). The fault cuts the Dark Thunder Canyon formation and the Bloodgood Canyon Tuff. An undeformed rhyolite dike has also been intruded along the fault at Raeburn Hills. Therefore the last movement along the Blue Bell fault must have occurred before emplacement of the rhyolite intrusive and quartz veins.

Production along the Blue Bell fault has occurred only at the Blue Bell mine (copper, gold, silver; Table 3.2), although the fault is silicified and stained with malachite, chrysocolla, and azurite along much of its length. The Blue Bell fault south of Raeburn Hills consists of massive to bladed, white quartz (locally pseudomorphed after bladed calcite) and bladed, white to clear calcite. North of Raeburn Hills only quartz is present. Shallow drilling by FMC at Raeburn Hills and by Nova Gold Resources, Ltd. (probably less than 200 m) south of Raeburn Hills failed to delineate any economic potential.

2.3.3.2. East Camp-Twin Peaks fault system—The East Camp-Twin Peaks fault system is one of the most prominent fault systems in the district (Fig. 2.3; Maps 1, 2). The fault begins near Blue Creek, southeast of the mapped area (Drewes et al., 1985) and can be

traced as one or more parallel to subparallel faults for approximately 30 km to the northwest, where it joins the Twin Peaks fault of Hedlund (1990a). It is finally cut off by a northeasttrending fault and covered by alluvium northwest of the mapped area.

The fault system strikes N50-55°W, but has numerous local variations, and typically dips steeply to the northeast but locally to the southwest as well (Fig. 2.15). It is downthrown to the northeast (Map 3). Throughout most of its length, the fault is silicified and mineralized and forms prominent outcrops. Rhyolite dikes intrude along the fault at the junction with the Carlisle fault, east and north of Telephone Ridge, and possibly at the Bank mine. Intense acid-sulfate alteration has obscured the lithologies at the Bank mine. Numerous mines occur along the fault system (Table 3.2). The fault typically exceeds 9 m in width and at the Summit mine the fault is 45 m wide at the surface (Fig. 2.16).

Displacement along and age of the East Camp-Twin Peaks fault system are uncertain. The fault cuts the Dark Thunder Canyon formation, the Summit Mountain formation, and a younger ash-flow tuff. In addition, the fault places acid-sulfate altered rocks adjacent to relatively unaltered Dark Thunder Canyon andesites north of Bitter Creek. This suggests a large displacement has occurred along the fault (>100 m). Hedlund (1990a) suggests total displacement is approximately 420 m but provides no evidence. The East Camp-Twin Peaks fault system also is intruded by rhyolite dikes and offsets other rhyolite dikes. Right-lateral ...strike separation of about 150-200 m is suggested north of Bitter Creek where the fault offsets a rhyolite dike (Maps 1, 2; Powers, 1976). Therefore, the East Camp-Twin Peaks fault system is probably of a similar age as the Blue Bell fault, i.e. older than the youngest rhyolite intrusives and quartz veins.

The East Camp-Twin Peaks fault system is cut by two shear zones in the mapped area: a shear zone near the Bank mine (Bank shear zone) and the Bitter Creek shear zone. Both shear zones are poorly exposed at the surface. The Bitter Creek shear zone is westnorthwest-trending. The Bank shear zone is concealed and has either an east or north trend. Both shear zones, described further in this section, have greatly influenced the distribution of

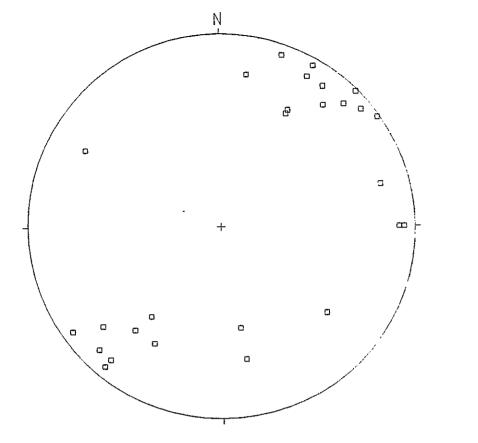

Figure 2.15—Stereonet of orientations of fault planes along the East Camp-Twin Peaks fault system (Schmidt projection, n = 30).

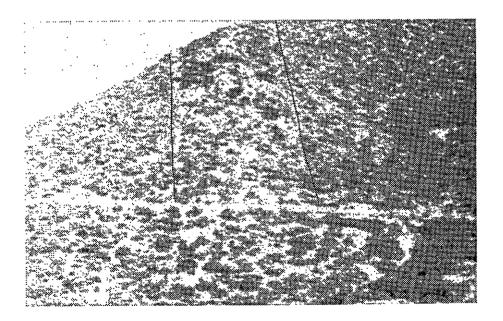

Figure 2.16—Photo looking at the East Camp-Summit fault which is up to 45 m wide. Located in roadcut just southeast of Bank mine (note head frame in lower right corner). Looking southeast.

mineralization along the East Camp-Twin Peaks fault system. Because of these shear zones and their effects on mineralization, it is convenient to divide the East Camp-Twin Peaks fault system into three segments (southwest to northeast): East Camp-Summit fault, Norman King-Billali fault, and Twin Peaks fault (Maps 1, 2). The Blue Bell fault merges with the East Camp-Twin Peaks fault near the Norman King mine.

The East Camp-Summit fault is the southeasternmost segment and is represented by numerous mines with significant production including the Thanksgiving, Davenport, McDonald, East Camp, Gold Nugget, Summit, and Bank mines. The fault extends northwestward past the Bank mine, where it is cut by the Bank shear zone. It is mineralized along most of the strike length in the mapped area (Map 2).

The middle segment is the Norman King-Billali fault which is a prominent, quartzfilled zone. This segment is mineralized along its entire length, from the Bank shear zone to the Bitter Creek shear zone and consists of numerous mines including the Billali, Hover Tunnel, Norman King, and Mohawk mines. North of the Mohawk mine, the Norman King-Billali fault is offset by the Bitter Creek shear zone.

North of the Bitter Creek shear zone, only one major fault of the East Camp-Twin Peaks system is exposed, the Twin Peaks fault. Much of this fault segment is also silicified and mineralized along strike, but rarely exceeds 6 m in width. Production has not been as significant along the Twin Peaks fault as from mines south of Bitter Creek. The Fraser and Black Willow mines occur along this fault segment.

South of the Bank shear zone, the East Camp-Twin Peaks fault system consists of the prominent East Camp-Summit fault on the southwest side of the Blue Bell zone of multiple, bifurcating quartz veins. All of the past production, except the Blue Bell mine, has come from mines along the East Camp-Summit fault. The Blue Bell mine is a copper-gold-silver mine with relatively minor production (Table 3.2).

North of the Bank shear zone, the East Camp-Twin Peaks fault system consists of a wide zone with three major faults. The northeastern fault is narrow and poorly exposed along

much of its strike length and may be the extension of the Blue Bell fault. It intersects the Norman King-Billali fault at the Mohawk mine. The middle and most prominent fault is the Norman King-Billali fault. The southwestern fault is poorly exposed, less than 1 m wide, and is only locally silicified and filled with quartz. All of the past production from mines between the Bank and Bitter Creek shear zones has been from mines that occur along the Norman King-Billali fault.

Several crossfaults have either caused minor bends or offsets to the faults of the East Camp-Twin Peaks fault system or are truncated by the fault system. Two minor east-west to northeast-trending faults southwest of the East Camp mine are truncated by the East Camp-Summit fault. A third fault northwest of the mines also is truncated by the East Camp-Summit fault. The west-northwest-trending Carlisle fault appears to be truncated by the East Camp-Summit fault, however the Carlisle fault did produce a small offset (less than 5 m) or bend in the East Camp-Summit fault. The Carlisle fault could not be found northeast of the East Camp-Summit fault. The Twin Peaks fault offsets two rhyolite dikes and the Twin Peaks plug.

2.3.3.3 Blue Goose fault—The Blue Goose fault, named for the Blue Goose mine, strikes N30-55°W and dips 65-80° southwest. It is downthrown to the southwest and is about 4-5 km long. To the south, the fault is not well exposed, although the fracture probably intersects the Apache fault near the Hext mine. Near the Goldenrod adit, the fault splits into two segments. The eastern segment strikes N10°W with a steep dip and an altered, silicified rhyolite dike has intruded along the fault. The western segment strikes northwest and splits; the western segment is the Center fault. Both segments intersect the Carlisle fault. The Blue Goose fault intersects the Carlisle fault near the Pennsylvania mine where the Bloodgood Canyon Tuff is brought down against clastic sedimentary rocks (Maps 3, 5). The displacement along the Blue Goose fault is probably less than 30 m, based on offset of the Bloodgood Canyon Tuff. The Blue Goose fault is older than the Carlisle fault and the rhyolite intrusive.

2.3.3.4 Apache fault—The Apache fault is south of the Carlisle fault and southwest

of the Blue Goose fault. It strikes N40-50°W and dips 60-70° southwest. It is downthrown to the southwest. The Apache fault begins near Blue Creek, southeast of the mapped area (Drewes et al., 1985), and trends northwest until it intersects the Carlisle fault at the Carlisle mine. The Apache fault produced a northwest-trending bend or offset in the Carlisle fault at the mine that localized mineralization (Map 5). The Apache fault cannot be traced north of the Carlisle fault, even though Hedlund (1990a) shows some faulting in that area. The Apache fault is approximately 12 km long along strike and, unlike most faults in the district, it is marked by several arroyos, including Possum Hollow. The fault is mineralized and silicified along portions of the strike length, however the only mine along the fault is the Hext mine (copper, gold, silver).

Displacement and age of the Apache fault are uncertain. Powers (1976) suggests displacement near the Hext mine is 450 m but provides no conclusive evidence. About one kilometer northwest of the Hext mine, a downthrown block of Dark Thunder Canyon formation overlying the Bloodgood Canyon Tuff is exposed on the southwest side of the fault. The Bloodgood Canyon Tuff is exposed to the east on a hill northeast of the Blue Goose fault. This suggests a total displacement produced by the two faults of only 150-200 m (Map 3). Rhyolite dikes intrude along the Apache fault south of the Hext mine, yet the Apache fault cuts a rhyolite intrusive northwest of the Hext mine. Therefore it is likely that the last movement along the Apache fault occurred during or after the rhyolite intrusive event.

2.3.2.5 Laura fault zone—The Laura fault zone lies east of Vanderbilt Peak and is approximately 3 km long. This fault zone strikes N30-50°W (Fig. 2.17) and merges with the Imperial fault (Steeple Rock fault of Hedlund, 1990a and Gillerman, 1964; Laura fault of Powers, 1976) to the east. The southern portion of the fault consists of several subparallel fault strands. Brecciated and fractured andesite occur between the various strands forming a zone up to 800 m wide. The Laura fault zone then converges to the northwest into one or two faults at the Laura mine (Fig. 2.18). The Laura fault continues to trend northwest until truncated by the Carlisle fault. The faults dip steeply, 80-85° southwest and are downthrown

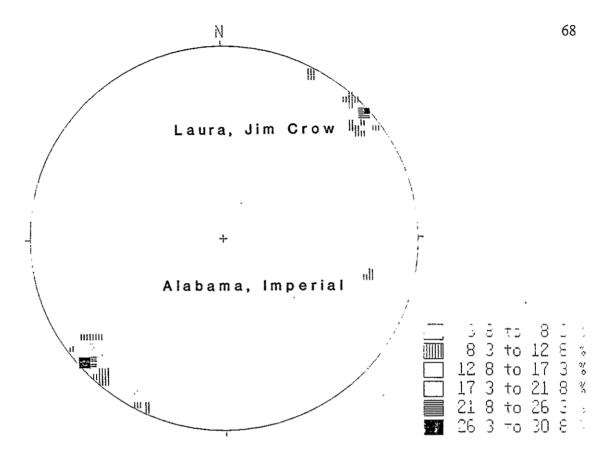

Figure 2.17—Stereonet of orientations of fault planes in the Laura-Jim Crow-Vanderbilt Peak area (step function, n = 26). Note the predominant northwest trend.

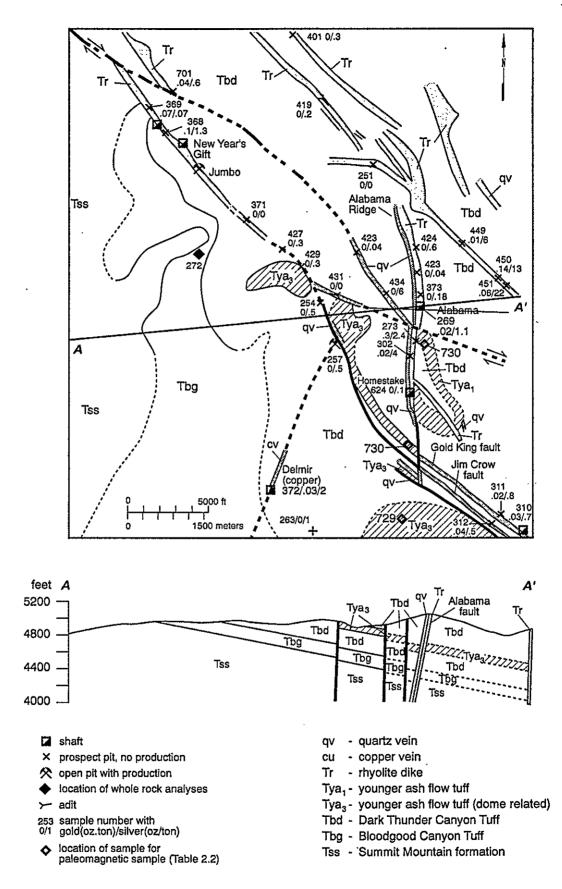

Figure 2.18—View of Laura Canyon from the air looking north. Note cap of Bloodgood Canyon Tuff (Tbg) on Rocky Top Ridge (to the right).

to the southwest. Rhyolite dikes and quartz veins commonly fill the various fault segments south of the Laura mine. The Laura, Big Horseshoe, and Smuggler mines occur along the fault zone. Assays along the faults suggest some mineral potential; one sample, #287, contained 0.18 oz/ton (6 ppm) Au and 3.5 oz/ton (120 ppm) Ag (Map 2; Appendix 11.6). A rhyolite dike and quartz vein southeast of the Smuggler mine may be the continuation of the Laura fault zone southeast of the Imperial fault, in which case there appears tobe some lateral displacement.

The fault zone places Dark Thunder Canyon formation adjacent to Summit Mountain formation. On Rocky Top Ridge, east of Laura Canyon, an ash-flow tuff, presumably Bloodgood Canyon Tuff, crops out (Fig. 2.18). This suggests that displacement along the Laura fault zone could be as much as 250-300 m. The fault is older than the rhyolite intrusives, quartz veins, and the Imperial fault.

2.3.3.6 Jim Crow-Gold King-New Years Gift fault zone—In the area of the Alabama, Jim Crow, and Imperial mines, south of Vanderbilt Peak, numerous northwest-trending faults of varying displacements and ages cut Dark Thunder Canyon formation, younger ash-flow tuff, and Summit Mountain formation. Rhyolite dikes and plugs are intruded along many of these faults and then subsequently offset by others (Maps 1, 2; Fig 2.19). Economically, the most important of these faults are the Jim Crow, Gold King, and New Years Gift faults. The Jim Crow and Gold King faults lie south of Alabama Ridge and merge with or are truncated by the Imperial fault. The Jim Crow fault is the southwestern fault, whereas the Gold King fault lies to the northeast and parallels the Jim Crow fault. The faults trend northwest and merge with the New Years Gift fault which continues northwestward to the Mulberry Springs area (Maps 1, 2). This entire area is highly fractured and faulted and structural interpretations are difficult at best.

In this area, these faults typically trend northwest with a strike of N45-65°W and a southwesterly dip of 75-85° to near vertical (Fig. 2.17). The faults are downthrown to the southwest and displacements are typically less than 30-50 m, based on displacement of the

ť:

', ---

. .

16

Figure 2.19 Geologic map of the Alabama Ridge and surrounding area

younger ash-flow tuff. Minor right lateral offset of about 30 m or less is suggested by offset of some quartz veins, indicating strike-slip or oblique-slip movement along some of the faults. The faults are typically filled by quartz and/or quartz-hematite breccia and are locally gold bearing (Map 2, Appendix 11.6).

2.3.3.7 Commerce-Mayflower fault—The Commerce-Mayflower fault is a prominent, curvilinear northwest-trending fault southwest of Noah Mesa in the northwestern part of the district. Powers (1976) called it the Mayflower fault, whereas Hedlund (1990a; Ratté and Hedlund, 1981) called it the Commerce fault. The fault strikes N60°W and dips 70-280° southwest. It is downthrown to the southwest. It can be traced from south of Cottonwood Creek, northwest of the mapped area, southeastward to north of Bitter Creek where the fault curves and subparallels the Bitter Creek shear zone. The fault may actually become part of the Bitter Creek shear zone, and is about 7 km long.

: ·: •

The fault throws Quaternary-Tertiary Gila Group clastic rocks adjacent to Summit Mountain formation northwest of the mapped area (Hedlund, 1993). In the mapped area, the fault cuts Summit Mountain formation, the Wampoo fluorite vein, and a rhyolite dike. Displacement along the Commerce-Mayflower fault is unknown, but presumed to be large $(\geq 100 \text{ m})$. Movement along this fault has been relatively recent as indicated by the Gila Group rocks.

Portions of the Commerce-Mayflower fault are silicified and filled with quartz and fluorite. Production from the Commerce-Mayflower mines has been insignificant.

2.3.3.8 Foothills fault zone—The Foothills fault zone of Powers (1976) occurs in the western portion of the mapped area, northwest of Goat Camp Springs area. It is a series of two or more faults with an average strike of N50°W with steep southwesterly dips (70-85°). The fault is interpreted to be downthrown to the northeast in order to bring younger rocks adjacent to older rocks (Map 3; Powers, 1976). The best exposures of the fault zone are along the western portion where thick quartz veins filled the fault segments and form prominent outcrops (Fig. 2.20). The fault zone is not as well exposed to the east (Map 1) and is inferred in most places (Map 2). The fault zone is covered by alluvium to the northwest of the mapped area (Hedlund, 1993) and is most likely truncated by a north-trending fault to the southeast. The fault zone is approximately 7 km long. It places Quaternary-Tertiary Gila Group adjacent to the Summit Mountain formation, northwest of the mapped area. Therefore the displacement along the fault is large (≥ 100 m) and movement along the fault is recent.

2.3.3.9 Fourth of July fault—The Fourth of July fault (Powers, 1976) is a minor, northwest-trending fault that probably intersects the Foothills fault zone northwest of the mapped area (Fig. 2.20). The fault cuts acid-sulfate altered rocks to the southeast. The Fourth of July fault is southwest of the Foothills fault zone and is filled by quartz, fluorite, and fault-breccia. It strikes N30-40°W and dips to the southwest 55-60°. It is downthrown to the southwest (Map 3) and is about 7 km long. Displacement along the Fourth of July fault is probably small.

2.3.4 North-trending faults

Very few faults in the Steeple Rock district have a northerly trend (Fig. 2.12; Table 2.4). Economically, the most important north-trending faults are the Imperial (Mt. Royal, Imperial, Smuggler mines) and the Alabama fault (Alabama, Homestake mines). A number of short, north-trending faults occur in the Goat Camp Spring, Willow Creek, Daniels Camp, and western Bitter Creek areas that localized rhyolite dikes and/or fluorite veins. A north-trending quartz-copper vein occurs east of Twin Peaks and is truncated by the Twin Peaks fault. The rhyolite plug at Twin Peaks is elongated in a northerly direction. Rhyolite dikes cutting Charlie Hill and near the Fraser mine also trend northward. Most of the north-trending faults are not long in strike length and many are truncated or offset by northwest-trending faults.

Griggs and Wagner (1966) and subsequently Biggerstaff (1974) and Powers (1976), map a north- to northeast-trending fault west of Telephone Ridge which they called the Summit fault. They offer no evidence for the fault, although Griggs and Wagner (1966) did

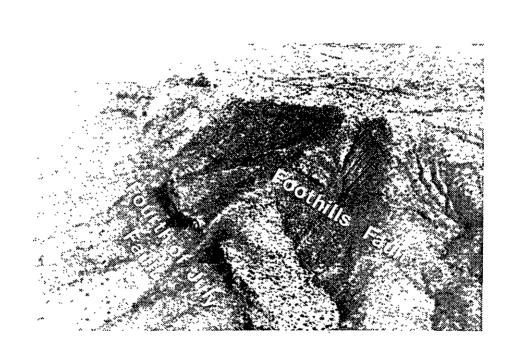

Figure 2.20-Aerial view of Foothills fault zone, looking toward the northwest.

<u>`</u>`

only infer its location. The only evidence for faulting in this area is the presence of acidsulfate altered rocks of the Summit Mountain formation. Hedlund (1990a) places an intrusive rhyolite in this region. Because of lack of field evidence supporting a fault, there are no faults mapped in this area on Maps 1 and 2.

2.3.4.1 Alabama fault—The north-trending fault at the Alabama mine strikes N10°W and dips 80° west (Fig. 2.17) and is one of numerous faults in the area (Fig. 2.19). The Alabama fault is about 450 m long and merges with northwest-trending faults at both ends. The fault cuts Dark Thunder Canyon formation and a younger ash-flow tuff. Rhyolite dikes and plugs have been intruded along much of the fault and are probably related to the rhyolite plug at Vanderbilt Peak. The rhyolite was subsequently silicified and locally mineralized. Displacement along the Alabama fault is approximately 40-50 m based on displacement of the younger ash-flow tuff (Fig. 2.19). The age of the fault is older than the rhyolite and mineralized quartz veins.

 \mathcal{L}

. (<u>*</u> *

47

÷.,

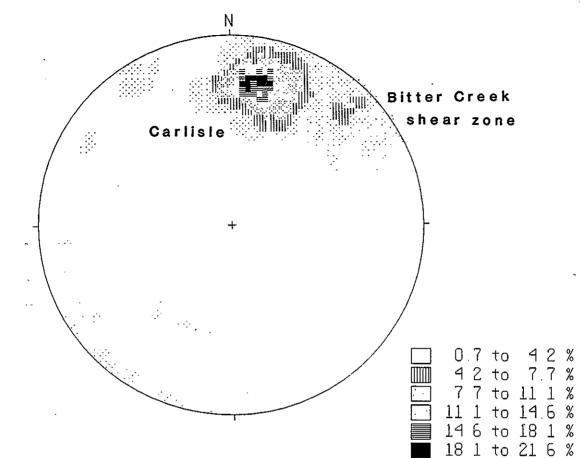

A northwest-trending crossfault offsets the Alabama fault 3 m south of the Alabama shaft (Fig 2.19). The crossfault strikes N70°W and dips 70° north. Subsurface mine maps indicate that this fault offsets the mineralized zone (Fig. 3.8; F. W. Smith, unpubl. report, 8/5/1910) and therefore must be younger than mineralization.

2.3.4.2 Imperial fault—The Imperial fault is a curvilinear, north-trending fault that lies east of Alabama Ridge and northwest of Mt. Royal. Hedlund (1990a) and Gillerman (1964) call this fault the Steeple Rock fault and Powers (1976) calls it the Laura fault. Elston (1960) labels a fault south of Mt. Royal and Steeple Rock the Steeple Rock fault. Therefore, to avoid further confusion, the fault in this report is called the Imperial fault after the Imperial mine, which is located in the southern part. The fault includes the Imperial, Mt. Royal, and Smuggler mines. The fault can be traced south-southwest of Mt. Royal where it is covered by alluvium and only inferred (Hedlund, 1990a). The fault trends north, partially following Carlisle Canyon, to south of Pennsylvania Canyon where it dies out. The fault truncates the northwest-trending Laura fault zone and Jim Crow and Gold King faults. The Imperial fault ranges in strike from N10°W to N20°E and dips to the west 70-85° (Fig. 2.17). The fault is downthrown to the west. It places the older rhyodacite of Mt. Royal and andesite of Mt. Royal on the east, adjacent to the Dark Thunder Canyon formation and a younger ash-flow tuff. The Imperial fault also offsets and truncates rhyolite dikes and quartz veins. The Imperial fault is filled locally with quartz, forming prominent outcrops; however, in many places the fault is poorly exposed. Displacement along the fault is uncertain but could be as much as 900 m, based on the displacement between the Dark Thunder Canyon formation and the andesite of Mt. Royal. Numerous splays and fault segments split off the main fault and in some places are too numerous to map at the scale employed. There are also numerous faults visible underground which are not exposed at the surface, causing locally wet, unstable ground conditions (Queenstake Resources Lt., unpubl. report, April 1982).

2.3.5 West-northwest-trending faults and shear zones

Several west-northwest-trending faults and shear zones occur in the Steeple Rock mining area (Figs. 2.12, 2.21; Table 2.4). At least three are important in the distribution of mineralization: Carlisle fault, Bank shear zone, and Bitter Creek shear zone. The Bank and Bitter Creek structures are called shear zones because they are not well exposed and actual displacement and fault surfaces are not well documented: However, these two areas are altered and sheared, indicating tectonic movement, and both zones substantially affect the distribution of mineralization, as previously discussed. The Carlisle fault is perhaps the most important fault economically in that most of the production from the Steeple Rock district has come from mines along it. Two additional west-northwest-trending faults are worth describing, the Crookson fault north of Bitter Creek and the Charlie Hill fault (part of the Foothills fault of Powers, 1976) in the southern part of the mapped area. A few rhyolite dikes in the Goat Camp Spring area and east of Charlie Hill also have a west-northwest trend.

2.3.5.1 Carlisle fault—The Carlisle fault is the major west-northwest-trending fault in the Steeple Rock district. The strike ranges from N75°W to N85°E with numerous local

موم. فرونس

<u>.</u>...

· ...

÷.,

à

Figure 2.21—Stereonet of orientations of fault planes along the west-northwest trending faults (step function grid, n = 148).

variations and it dips 60-70° to the south (Fig. 2.21). The fault can be traced from the East Camp-Summit fault westward past Laura Canyon, where it curves northwest. The fault eventually is covered by alluvium west of the mapped area (Hedlund, 1993). Hedlund (1990a, c) calls the western portion of the fault the Whiskey Creek fault. For the purposes of this study, the entire fault is called Carlisle after previous workers and it is suggested that the term Whiskey Creek fault be discontinued.

The Carlisle fault is a prominent quartz-breccia vein or silicified zone along much of its strike, however it appears to be mineralized only from the Carlisle mine eastward to the Ontario mine (Map 5). Additional mineralized zones also occur in section 2, west of the Carlisle mine. The fault is downthrown to the south and has variable displacement. It varies in width from less than one to 30 m. Locally, two parallel or subparallel fractures are present; both constitute the Carlisle fault.

West of the Pennsylvania mine, near the intersection with the Blue Goose fault, the displacement is approximately 210 m; west of the Apache fault the displacement is approximately 270 m (Map 3; Griggs and Wagner, 1966). The Carlisle fault has a displacement of as much as 610 m west of the Laura fault where Dark Thunder Canyon formation to the south is adjacent to Summit Mountain formation to the north. Further to the west where the Carlisle fault cuts a rhyolite dome west of Saddleback Mountain, the displacement is only 140-180 m. The difference in displacement is the result of northwest-trending faults, downthrown to the south that are truncated by the Carlisle fault. Oblique movement is also indicated by fault slickensides plunging 45-60°SW. The Blue Goose and Apache faults do not offset the Carlisle fault, but produce bends in the Carlisle fault, suggesting that movement along these northwest faults occurred after formation of the Carlisle fault. These bends localized mineralization and are evidence of different periods of oblique-slip movement.

2.3.5.2 Bank shear zone—A poorly exposed shear zone north of the Bank mine has affected the distribution of mineralization along the East Camp-Twin Peaks fault zone.

Alteration of the area in the vicinity of the Bank mine, which is either related to the shear zone or to early acid-sulfate alteration, has obscured lithologies and any traces of faults. This shear zone exists primarily because of the change in character of mineralization along the East Camp-Twin Peaks shear zone (previously discussed). The zone is characterized by gouge zones, brecciated and fractured country rocks, and acid-sulfate alteration. This zone continues at depth as an unaltered, poorly consolidated shear zone. Geologists of Biron Bay Resources Ltd. believe that the zone trends east-west based on subsurface data. Mapping for this project revealed a north-south fault (N10°W to N20°W), filled with quartz that cuts the East Camp-Summit fault, however this fault could not be traced along strike for any distance. Therefore the Bank shear zone cannot be plotted on Maps 1, 2 with any certainty.

· .

÷.,

' <u>}</u>:

Displacement, if any, and age of the zone are unknown. More will be discussed about this zone under alteration (section 5).

2.3.5.3 Bitter Creek shear zone—The Bitter Creek shear zone, first recognized by Powers (1976), occurs along Bitter Creek north of Saddleback Mountain. This zone strikes west to northwest (Fig. 2.21) and is characterized by parallel to subparallel fault segments, fractured and brecciated country rock, gouge zones, and offsets of rhyolite dikes and the East Camp-Twin Peaks fault system.

In the western Bitter Creek area, the Bitter Creek shear zone consists of two or more west-northwest-trending faults. These faults are locally filled with quartz veins with local pyrite and fluorite. The Commerce-Mayflower fault curves north of Bitter Creek and may be part of the shear zone. Although dips cannot be measured, the zone probably dips steeply to the north because of displacement of the altered rocks north and south of the zone (Map 3). A drill hole near the Recent spring deposit (Bitter Creek #1 drill hole) intersects several quartzfluorite veins at depth which could represent part of this shear zone. The Recent spring deposit overlies one segment of the fault and it has not been faulted.

The Bitter Creek shear zone changes character to the east, where discrete fault zones are not exposed. Areas of fractured and brecciated country rock and gouge zones are typical of the fault trace. The shear zone has also laterally offset a rhyolite dike and the East Camp-Twin Peaks fault system approximately 300-600 m. Vertical displacement is unknown.

The Bitter Creek shear zone is not mineralized except for a few local areas along the western portion and in the Bitter Creek #1 drill hole (Appendix 11.1). However, the zone offsets the Powell and Leta Lynn fluorite veins as well as the East Camp-Twin Peaks fault system. Most of the production along the East Camp-Twin Peaks fault system has come from mines south of the shear zone. Only the Fraser and Black Willow mines occur along the Twin Peaks fault north of the Bitter Creek shear zone.

2.3.5.4 Crookson fault—The Crookson fault of Biggerstaff (1976) is north of Bitter Creek, averages N85°E in strike, and parallels the Bitter Creek shear zone. The fault is approximately 7 km long and extends to the east beyond the mapped area (Hedlund, 1993). The fault is truncated by or merges with the Twin Peaks fault at mine #1002 (Map 2) and trends easterly to Cherry Creek and beyond. The fault is poorly exposed along most of its strike in the mapped area and is characterized by local zones of closely spaced west-trending joints and minor brecciation. Apparently the fault is better exposed to the east (Biggerstaff, 1974; Powers, 1976).

The fault offsets several outcrops of altered sandstones of Dark Thunder Canyon formation. At mine #1002, fractures and thin quartz veins strike east-west for several meters east of the mine. Mine #1002 is actually part of the Twin Peaks fault. Hedlund (1993) suggests that the fault is downthrown to the south (Map 3), but dips could not be measured because of poor exposure. The fault cuts Dark Thunder Canyon formation and lava flows of Crookson Peak and thus is younger than the lava flows of Crookson Peak (27.6 \pm 2 Ma, fission track age on zircon, D. E. Hedlund, unpubl. report, 1990). Displacement along the fault is probably small. The fault appears to have no effects on mineralization, except perhaps at depth at mine #1002. This needs to be tested at depth by drilling.

2.3.5.5 Charlie Hill fault—The Charlie Hill fault is a poorly exposed westnorthwest-trending fault that lies north of Charlie Hill in the southern portion of the mapped area (Maps 1, 2). The fault is probably less than 3 km in length and strikes N70°W to N80°E with a steep dip (80°S to 80°N). The fault offsets Bloodgood Canyon Tuff east of Charlie Hill. Displacement along the fault is approximately 50-60 m, where it cuts the Bloodgood Canyon Tuff. The fault is downthrown to the north. Right-lateral offset is indicated along the western edge of the Charlie Hill fault where a rhyolite dike is offset along strike approximately 90-100 m, suggesting strike-slip or oblique-slip movement. Parts of the fault are filled with quartz and/or clay, however it is relatively unmineralized along most of its strike length.

2.3.6 Northeast-trending faults

Northeast-trending faults are extremely rare in the Steeple Rock district (Maps 1, 2; Fig. 2.12; Table 2.4). A few rhyolite dikes north of Twin Peaks fault trend N30-40°E to north-south (Fig. 2.11). Several minor faults in the Goat Camp Spring area also trend northnortheast and are filled with quartz, quartz-fluorite, and/or rhyolite dikes. These typically are downthrown to the northwest with minor displacement. The Delmir fault, containing the Delmir copper mine, strikes northeast and is cut off by the Charlie Hill fault to the southwest and the Jim Crow fault to the northeast (Fig. 2.19). It is downthrown to the northwest and displacement is small.

Southwest of the Imperial fault, Hedlund (1990a, c) maps a curvilinear, eastnortheast-trending fracture he called the Carlisle Canyon fault. He further suggests that the supposed Carlisle Canyon fault is a ring fault, but provides no conclusive evidence. This fault is not located on Maps 1 or 2 because of lack of field evidence in the mapped area to support the occurrence of a fault. However, this area should be re-examined in greater detail to determine if Hedlund's fault exists to the south.

2.4 Petrochemistry

Samples of various volcanic, volcaniclastic, and intrusive rocks from throughout the

Steeple Rock district were analyzed for major and trace elements. Geochemical data, including selected published data, are in Appendix 11.4 and sample locations are on Map 2. The samples are grouped according to lithology and mineralogy as rhyolite/rhyodacite intrusives, ash-flow tuffs, andesites and related volcaniclastic rocks, and acid-sulfate altered rocks. Methods of analyses, detection limits and estimates of error are discussed in section 1.5.4 and Table 1.3.

Despite variable intense alteration, the Steeple Rock samples are grossly similar in chemical composition to similar lithologies elsewhere in the Mogollon-Datil volcanic field (Bornhorst, 1980, 1986, 1988; Sharp, 1991). The Steeple Rock samples are predominantly peraluminous (i.e. $Al_2O_3/(CaO + K_2O + Na_2O) > 1.0$), high K, silica-saturated, calc-alkaline basaltic andesite to rhyolite. Most of the Steeple Rock samples are subalkaline and form trends typical of calc-alkaline igneous rocks, according to the definition of Irvine and Baragar (1971). However, a few andesites plot in the alkaline field, probably as a result of alteration (Fig. 2.22).

Igneous petrologists commonly compare geochemical data to various studies that relate chemical compositions of igneous rocks from throughout the world to plate tectonic settings. A study by Pearce et al. (1984) establishes that igneous rocks formed in various tectonic settings have different chemical signatures. Pearce et al. (1984) refers to these settings as ocean ridge, volcanic arc, syn-collision (formed by collision of two plates), and within-plate fields. Rocks formed in these tectonic settings are characterized by well defined fields on chemical variation plots. Most Steeple Rock andesites plot within the volcanic arc or syn-collision fields. Most of the Steeple Rock rhyolites and ash-fow tuffs plot near the tectonic fields of volclanic arc, syn-collision, and within-plate (Figs. 2.23, 2.24). The similarity in chemical composition of rocks in the Steeple Rock district to the composition of rocks formed in volcanic arc, syn-collision, and within-plate tectonic settings infers that the Steeple Rock rocks were formed in complex tectonic settings related to the subduction of lithospheric crust. These chemical trends are consistent with current theories of the tectonic

 evolution of the Steeple Rock area as discussed in section 2.3.

Geochemistry is also utilized in classifying volcanic rocks. However, geochemical classifications are not adequate to describe the Steeple Rock samples because of the variable intensity of alteration. The TAS (total alkali-silica) diagram is widely used in classifying volcanic rocks (Le Bas et al., 1986). However, only the rhyolites and ash-flow tuffs from the Steeple Rock area plot in the correct field (Fig. 2.22). The andesites are scattered throughout the diagram because of addition of silica and remobilization of alkalis. A similar scatter is observed in the popular R_1 - R_2 classification scheme by De La Roche (1980). Winchester and Floyd (1977) developed a classification scheme on the basis of Zr/TiO₂ and Nb/Y, because these elements are typically immobile during alteration. Most Steeple Rock samples plot in or near their respective lithologic fields (Fig. 2.25): rhyolites as rhyolites or rhyodacites and andesites as andesites or rhyodacites/dacites.

Geochemical data indicate that the andesites are more altered than the rhyolites or ash-flow tuffs. The ash-flow tuffs and rhyolites have similar chemical compositions. Interpretation of magmatic differentiation trends on the basis of chemistry is not possible, because the rocks in the Steeple Rock district are too altered. Finally, petrochemical theories pertaining to the origin and genesis of the Steeple Rock samples cannot be established with these data because of the variable intensity of alteration.

2.5 Water Resources

Water resources in the Steeple Rock district are not abundant except locally along faults. The streams and few springs in the area are ephemeral and depend upon local precipitation. Annual precipitation is typically less than 40 cm/yr, although wet years with higher rates do occur (Trauger, 1972). The Steeple Rock district, as part of the Summit Mountains, is one of many recharge areas for the Gila valley. The ephemeral streams enter the Gila River.

There are no major aquifers in the district. Water occurs along fractures, bedding

.

planes, and faults. Most windmills in the district are situated along faults, with a few exceptions (Fig. 2.26). The sedimentary rocks in the area are relatively thin and may provide local but small quantities of water. Most mines contain substantial quantities of water and must be pumped. A few mines and windmills can sustain pumping rates of 1.6 liters per second (25 gallons per minute), but most pumping rates are less (Trauger, 1972). The Center mine pumps 5 liters per second (80 gallons per minute) for 3½ hrs/day. The depth to water in the mines and along faults varies from 2 to 73 m according to elevation and annual precipitation. The Carlisle mine is flooded below 25 m. Silicification along most faults restricts migration of groundwater, especially away from the faults into the country rocks.

Chemical analyses of water samples typically exceeds EPA guidelines or standards for drinking water (Table 2.5; Fig. 2.26); most of the water in the district is of suitable quality for livestock, irrigation, and some industrial uses. Some water is used for domestic purposes without any ill-effects. Most of the water from mines, except for the Carlisle mine, is also suitable for these purposes. The water at the Carlisle mine is acidic and contains elevated levels of iron, copper, lead, and zinc (Table 2.5). The quality of water deeper in the Carlisle mine is unknown and must be tested prior to dewatering.

3. MINING HISTORY AND DESCRIPTION OF MINES

3.1 General mining history and production

The earliest mention of mining activity in the Steeple Rock district was a report of a military dispatch of troops from Ft. Thomas (near Duncan, Arizona) in 1860 to assist miners in the area from interference by Apache Indians (Russell, 1947). The earliest production reported from the district occurred in 1880 when a 20-stamp amalgamating mill was erected at the Carlisle mine. By 1886, the mill was enlarged to 60 stamps. The first mining claims were filed in January 1881, and included the Carlisle, Star of the West, Center, and Pennsylvania (Table 3.1; Griggs and Wagner, 1966). Prior to 1904, accurate production records were not kept by any government agency, therefore production is only estimated from old mining records. In addition, many early records were lost in the San Francisco earthquake in 1906 (NMBMMR file data). The Carlisle mine was the largest producer and most of the estimated production prior to 1904, amounting to about 112,000 tons, is attributed to the Carlisle mine.

By 1897, most of the mines in the district were located and operated by several different companies (Table 3.1, 3.2; Fig. 3.1). Open stope mining was employed in most mines, although shrinkage stope methods were used locally. Square-set mining was also used in some of the East Camp mines. Small shipments, some high grade in gold and silver, were made from many of the mines but total production was small. Herbert Hoover worked in the district in the late 1890s as a mining engineer before becoming President of the United States (Gillerman, 1964).

In 1933, the price of gold rose from \$20.67 to \$35 per ounce and many of the mines in the district were re-examined for gold potential. Several mines operated over the next few years (Table 3.2). From 1934 to 1942, total production from the district amounted to about 30,000 ounces of gold and over 1 million ounces of silver (Table 1.2; Griggs and Wagner, 1966); most of this production came from the East Camp mines.

In 1942, the federal government closed all gold-silver mines as a result of World War II. Men were needed elsewhere and only base-metal mines were allowed to operate. The

USBM evaluated the Carlisle, Center, and Pennsylvania mines, including sampling of the underground workings and drilling, to determine the potential for base metals (Russell, 1947; Griggs and Wagner, 1966). Drill core from this project is stored at the USGS core facility in Denver, Colorado. From 1942 to 1946, total production from these mines amounted to more than 8 million pounds of copper, lead, and zinc (Table 3.2). These ores were first processed in Duncan and then, in 1944, the ores were processed at the rehabilitated East Camp mill. Processing of ore from the Carlisle mine at the East Camp mill resulted in some confusion in production records and assays of mine dumps. Contamination of East Camp dumps occurred and some of the ore attributed to East Camp mines may have actually come from the Carlisle mine.

<u>ن</u> د

Some of the fluorite mines in the western part of the district operated in the 1930s and 1940s and again in the 1970s (Table 3.2). About 11,000 tons of fluorite were produced (Hedlund, 1990a). Manganese from the western part of the district was also produced (Keith et al., 1983). Most of this production was minor.

Production and exploration between 1947 and 1980 were minor (Table 3.2, 1.2). In 1954, Kennecott Co., presumably looking for porphyry copper deposits, drilled a hole in the Bitter Creek altered area (Bitter Creek #1, sec. 20 T16S R21W, Appendix 11.1) to a depth of 762 m (Hedlund, 1990b; Powers, 1976; W. M. Sheperd, pers. comm. April 1993). Exploration drilling occurred periodically throughout the district from 1950 to 1980 (Hedlund, 1990b; unpublished company reports). Drilling occurred at the Carnation mine in 1959-60 and at East Camp in 1965 (Banner Mining Co.) and again in 1973 (Mt. Royal Mining Co.). Dresser Industries Inc. drilled at the Center mine in 1977-79 (Appendix 11.1). Douglas Hansen rehabilitated and intermittently shipped ore from the Summit, Center, Bank, Laura, Carlisle, and East Camp mines in 1975-90. In 1980, Queenstake Resources Ltd. (Canada) examined the Jim Crow, Gold King, and Imperial mines and holes were drilled in 1985 and 1987 (Appendix 11.1). Calculated reserves were reported as 155,535 tons of ore averaging 0.11 oz/ton (4 ppm) Au and 3.45 oz/ton (118 ppm) Ag (Queenstake Resources Ltd., press release, 4/2/87).

Exploration intensified in the 1980s and into the 1990s but not much production has occurred (Table 3.2). Superior Mining Division drilled in the Bitter Creek altered area (sec 27 T16S R21W) to 274 m. FMC drilled an altered area along the Blue Bell fault at Raeburn Hills east of Telephone Ridge in 1987 (Appendix 11.1). Impala Resources Ltd. (Canada) drilled at East Camp in 1986. Inspiration Mining Co., Phelps Dodge Inc., Hecla Mining Co., St. Cloud Mining Co., Noranda Exploration, Inc., and Pioneer Nuclear Corp. also had exploration projects in the district in the 1980s. Pioneer Nuclear Corp. drilled at Telephone Ridge in 1984-86. Results of these programs are largely unknown but did not result in any mining or announcement of major discoveries. Dresser Industries, Inc. drilled at the Center and East Camp mines; results are unknown except at the Center mine where production began in 1987.

In 1987, R and B Mining Co. obtained a lease from Mt. Royal Mining Co. (Houston, Texas) and began mining at the Center via a decline. The mine has produced silica flux with significant gold and silver since 1987. In 1988, Nova Gold Ltd. (Canada) initiated exploration of the Summit vein. A joint venture with Biron Bay Resources Ltd. (Canada) was formed in 1990 and drilling continued with proving of ore reserves. Biron Bay announced the discovery of a deposit containing 1,450,000 tons of ore grading 0.179 oz/ton (6 ppm) Au and 10.26 oz/ton (398 ppm) Ag for a width of 4 m (Petroleum and Mining Review, May 1992, p. 2). Additional exploration drilling is planned for 1993.

In July 1991, Great Lakes Exploration Co. (Minnesota) drilled at the Alabama (Appendix 11.1). This drill core is stored at NMBMMR, Socorro, New Mexico. Douglas Hansen shipped ore from the East Camp. A Canadian firm drilled at the Carlisle mine in August 1991 (Appendix 11.1). Cuttings are stored at NMBMMR. Mining for gold-silver flux continues at the Center mine; some ore shipments assay as much as 0.8 oz/ton (27 ppm) Au and 5 oz/ton (171 ppm) Ag.

Numerous abandoned shafts, pits, trenches, and adits occur throughout the Steeple Rock district (Maps 1, 2). Some are accessible, but many are dangerous and should be avoided. Only adits and shallow shafts with competent ground were examined during this study using proper equipment and accompanied by additional trained personnel. The district is dry most of the year. Groundwater is found only along major faults.

The mines can be grouped according to predominant mineralogy as base-metal mines, gold-silver mines, copper-silver mines, fluorite mines, and manganese mines. In addition, the district may contain alunite (Hall, 1978) and clay resources. These commodities have not been exploited in the Steeple Rock district, but are described under economic potential. At least two quarries in sec. 23, T16S, R21W and sec. 6, T17S, R20W were mined for decorative stone, but no production figures are available. The district also has been examined for molybdenum, porphyry copper, and uranium (see economic potential). The following descriptions of the more important deposits are from field observations and published and unpublished reports, as cited. Lack of proper exposure of some deposits hampered field descriptions locally. Not all mines could be properly described because of poor exposure and dangerous, abandoned workings.

3.2 General description of vein deposits

In the Steeple Rock district, the vein deposits occur exclusively along faults and fractures within fault zones. Some vein deposits occur along, and cut across, rhyolite dikes and plugs which are intruded along faults. In some places, later faults offset the vein deposits and rhyolite dikes (Maps 1.2). The veins typically form prominent outcrops and are bifurcating, sinuous, and pinch and swell along strike. Complex vein textures, especially brecciation and rhythmic layering, are typically associated with high metal concentrations, although many complexly-textured veins are barren of any mineralization. At least four stages of mineralization separated by periods of brecciation occurred: stage 1, stage 2, stage 3, and late stage mineralization. Additional information concerning paragenesis will be discussed in section 6.4.

Five types of vein deposits are distinguished on the basis of mineralogy and metal

content: base-metal (silver- \pm gold), gold-silver (\pm base metals), copper-silver, fluorite, and manganese veins. A sixth type of deposit, high-sulfidation disseminated gold deposits, may also occur in areas of acid-sulfate alteration.

The age of the vein deposits in the Steeple Rock district is problematical. Wahl (1983) reports a K-Ar age on adularia from the East Camp vein as 18 Ma. Veins cut the Bloodgood Canyon Tuff and younger ash-flow tuffs and therefore must be younger than 27 Ma. The age of the vein deposits will be discussed in more detail later in this report.

3.2.1 Base-metal veins

The base-metal veins in the Steeple Rock district occur exclusively along the Carlisle fault, from the Carlisle mine eastward to the Ontario mine (Maps 1, 2). These veins consist of 5–20% sulfides as galena, sphalerite, and chalcopyrite with considerable silver and gold and local secondary sulfide and carbonate minerals in a gangue of quartz, pyrite, chlorite, illite/sericite, rare adularia, and a few additional accessory minerals. Sulfide minerals vary in concentration throughout the fault zone, as they occur in two or three ore shoots and appear to increase with depth, then decrease near the base of the mineralization. Early reports indicate that gold and silver with only trace amounts of base metals occurred near the surface of the Center and Pennsylvania mines and graded with depth to base-metal veins. Base metals occur at the surface at the Carlisle mine, however, early reports show gold and silver were also concentrated in a separate ore shoot (Griggs and Wagner, 1966).

The ore occurs as 1) coarse-grained, massive sulfides (up to 20% base metals total), locally with little quartz, and 2) medium- to fine-grained sulfides disseminated throughout the brecciated quartz veins and fault gouge. Sulfides in the massive zone occur as streaks, irregular masses, and veinlets in zones up to 4 m across. Banded, rhythmic layering, and brecciated textures are characteristic. At least three periods of brecciation and cementation by silica have occurred. Sulfides occur in stage 2 mineralization and locally in stage 3. Lenses or zones of chlorite locally occur between bands of sulfides. Alteration is variable but typically silicification, chloritization, and clay alteration is well developed along and between the veins. Acid-sulfate alteration occurs at the surface at the Carlisle and Ontario mines.

3.2.2 Gold-silver veins

The precious metal veins in the Steeple Rock district consist of gold and silver with local but minor sulfides (less than 1%) as pyrite, galena, sphalerite, and chalcopyrite disseminated in a gangue of quartz, calcite, chlorite, illite/smectite, rare adularia, epidote, and additional accessory minerals. These veins are predominantly quartz and quartz breccias and occur along the northwest-trending faults, but they may occur along any fault trace. They grade along strike locally with the Carlisle base-metal veins, fluorite veins, and copper-silver veins. Base-metal sulfides occur at depth in many of these deposits, but total base metals rarely exceed 1-3%. In two deep drill holes near the Mohawk mine, zones of disseminated galena, sphalerite, chalcopyrite, and pyrite occur in silicified porphyritic andesite. Up to 5% sulfides have replaced feldspar phenocrysts and the groundmass.

The best gold-silver values occur in complex veins that are banded, rhythmically layered, and brecciated. At least three periods of brecciation and cementation by silica has occurred in many areas. Gold and silver occur in stage 2 and locally in stage 3. Lattice textures are locally common. A yellow to yellow-green staining of mottramite $(Cu,Zn)Pb(VO_4)(OH)$ or mimetite $Pb_5(AsO_4,PO_4)_3Cl$ is characteristic of higher values of gold and silver. Sulfides tend to occur in streaks or thin zones of disseminated sulfides and give the quartz a bluish or black tint. Distinction between mineralized veins and barren veins is difficult and confirmed only by fire assays.

3.2.3 Copper-silver veins

1.5

The copper-silver veins are characterized by secondary copper minerals, predominantly malachite and pseudomalachite, with detectable silver concentrations and rare gold concentrations. These veins are sporadically distributed throughout the district and locally grade laterally and vertically with gold-silver or fluorite veins (Map 2). The coppersilver veins have not been major producers of ore, although some deposits have yielded minor quantities of ore in the past (Table 3.2).

The copper-silver veins are typically short, rarely exceeding a few tens of meters in length. Malachite, pseudomalachite, azurite, chalcanthite, chalcocite, chrysocolla, and other secondary copper minerals are prevalent along fractures and cracks within fault zones. The faults typically trend north to northwest to northeast. Gangue minerals include quartz, calcite, and clay minerals and locally iron and manganese oxides. In contrast to the base-metal and gold-silver veins, the copper-silver veins are simple fissure-filling or fracture-coating deposits. Locally the veins may be zoned with quartz forming the outer portions and quartz, calcite, and copper minerals forming the cores of the veins. Either one period of or no brecciation occurred. Silicification is not as extensive as in the base-metal and gold-silver veins. Pyrite, malachite, and chalcopyrite may occur disseminated through the silicified host rock for several meters distal from the veins.

3.2.4 Fluorite veins

The fluorite veins in the Steeple Rock district occur predominantly along the western edge of the district and along Bitter Creek. These veins are typically simple fissure-filling or fracture-coating of fluorite with minor quartz and calcite. In general, they occur along splays of major faults and along minor faults (Maps 1, 2).

3.2.5 Manganese veins

m.ä.

Manganese oxides, typically psilomelane, occur as late-stage coatings along with other vein minerals throughout the Steeple Rock district. Locally manganese oxides form thin veins and fracture-fillings up to 10 cm thick. The Black Cat deposit in the Foothills fault area is the single locality where manganese was mined and produced in the 1950s. This zone is up to 3-5 m wide. Fluorite is an accessory mineral and silicification is common.

3.2.6 Disseminated gold deposits(?)

Disseminated gold deposits (high sulfidation) are associated with acid-sulfate altered rocks in several mining districts in the world, such as Round Mountain, Nevada (Tingley and Berger, 1985), Pueblo Viejo, Dominican Republic (Kesler et al., 1981; Muntean et al., 1990; Vennemann et al., 1991, 1993), Summitville, Colorado (Perkins and Nieman, 1983; Stoffregen, 1987; Rye et al., 1992) and El Indio, Chile (Walthier et al., 1982). These deposits are characterized by gold, pyrite, and enargite in vuggy silica, veinlets, stockworks, and breccias in zones of acid-sulfate altered rocks. Bonanza veins are common, but deposits of fine-grained gold disseminated in the host rock are also common (Cox and Singer, 1986; Heald et al., 1987; White and Hedenquist, 1990).

The intense acid-sulfate alteration cropping out locally in the Steeple Rock area indicates a potential for similar gold deposits. Although no disseminated gold deposits yet have been found in the Steeple Rock area, at least two companies (Pioneer Nuclear and FMC) have drilled in altered areas, presumably exploring for similar deposits (Appendix 11.1). Although drilling is inconclusive, a few assays of the drill core are indicative of the presence of gold. Furthermore, surface samples collected for this study also contain gold locally and are indicative of disseminated gold deposits (Appendix 11.5, 11.6). Further discussions of this type of deposit are in section 5 of this report.

3.3 Description of base-metal mines

3.3.1 Carlisle mine

The principal mine in the Steeple Rock district is the Carlisle mine and much of the production from the district is attributed to this mine. The Carlisle mine is located on the Carlisle fault at the junction with the Apache fault in sec. 1, T17S, R21W (Maps 1, 2, 5).

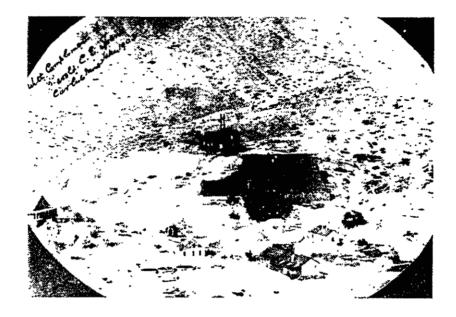

Although there was reported production from the mine prior to 1880, the first mining claims were not filed until 1881. In January 1881, Daniel Remington, James Mounts, William Johns, and A. G. P. George from Carlisle, Pennsylvania, filed four claims: Carlisle, Star of

the West, Center, and Pennsylvania. In 1883, the Carlisle group of claims was sold to a group of Chicago merchants who formed the Carlisle Mining Co. In January 1887, the Carlisle Mining Co. was sold, reportedly for \$1 million, to a group of London investors. From 1880 to 1890 total production is reported as \$4 million of gold and silver (R. Blanchard, unpubl. report, 8/20/28). The new company developed the Carlisle mine to 183 m depth, via a winze on the 152-m level and enlarged the mill from 20 stamps to 60 stamps. Ore from throughout the district was processed at the Carlisle mill. In 1887, a smelter was built and attempted unsuccessfully to recover lead and zinc from the mine.

The mine closed in 1890 when the easily recoverable gold and silver orebodies were exhausted. Although gold and silver were found in the lead-zinc sulfide orebodies, the sulfide ore could not be processed at this time. Attempts at recovering the sulfides and gold and silver were unsuccessful until the 1900s. By 1892, only 10 stamps remained operating at the mill. The Steeple Rock Development Co. was organized in 1896 and assumed the assets of the Carlisle Mining Co. The mine was reopened in the 1890s and again in 1904 and 1913, but only minor production occurred. Figures 3.2 and 3.3 are photographs of the Carlisle mine area in the early 1900s.

From 1876 to 1914, the Steeple Rock Development Co. consolidated numerous claims throughout the district and milled much of the ore at the Carlisle mill. However, as silver prices dropped, the company was forced to sell off portions of the properties. In 1914, George H. Utter bought the remaining assets, including the Carlisle and began processing mill tailings at the Carlisle until 1920. Utter may have produced from the Carlisle mine during 1914-1920 as well. In 1927, United Metals Corp. dewatered the Carlisle and continued development. By 1928, total development consisted of approximately 3000 m of drifts, crosscuts, winzes, raises, and the 158-m shaft (R. Blanchard, unpubl. report, 8/20/28). The ultimate depth reached in the mine is 219 m.

The mine closed again in 1930. In 1936-1941, Veta Mines, Inc. and other lessors operated the mine. Minor production occurred. In 1941-1942, Southwest Minerals Co.

produced from the Carlisle (Gillerman, 1964). The U.S. Bureau of Mines examined the mine and other operating mines from 1942 to 1944 in response to government directives as a result of World War II. Description of drill core data is in Appendix 11.1. The East Camp Syndicate, Inc. (later the Exploration Syndicate, Inc.) leased and operated the Carlisle mine from 1943 to 1946. The mine closed again in 1951 and was allowed to fill with water to the 61-m level. Some production occurred from the open pit in 1954, 1960, 1970s, 1982, and 1989-1990.

The Carlisle mine, now flooded, consists of a three-compartment shaft (157 m deep) with a winze on the 152-m level to 219 m total depth. Levels are reported at 12, 49, 61, 76, 91, 102, 122, 137, 152, 183, and 213 m. Mine maps are in Griggs and Wagner (1966) and a longitudinal section is on Map 5. An open pit with a decline connects to the 12-m level. A second short adit occurs on the west side of the pit (Fig. 3.4).

The Carlisle orebodies occur at the junction of the normally west-northwest-trending Carlisle fault and the northwest-trending Apache fault. The Apache fault has caused the Carlisle fault to strike locally N45°W with a 65-80°S dip (Fig. 3.5). The Carlisle fault resumes a more westerly strike about 30 m east of the shaft and 243 m west of the shaft (Map 1, 2; Gillerman, 1964). The Carlisle orebodies are within the northwest-trending segment.

The host rock is altered andesite and andesite porphyry of the Summit Mountain formation. Rhyolite ash-flow tuffs are probably present but the alteration is too intense to be certain. The orebodies occur in one to three major breccia veins consisting of rock fragments, quartz, pyrite, illite, kaolinite, chlorite, and adularia (Fig 3.6). The surface ore minerals include oxidized copper and lead minerals, whereas galena, sphalerite, chalcopyrite, bornite, and chalcocite are found in the mine. Ore shoots are pods, stringers, and irregular masses within the breccia veins. Some shoots were up to 2.4 m wide and 61 m long (Gillerman, 1964). Base metal concentrations increased with depth (Gillerman, 1964; Griggs and Wagner, 1966). Drilling by the U.S. Bureau of Mines on the 213-m level did not indicate reserves at depth (Griggs and Wagner, 1966), however, early descriptions suggest not all reserves were

mined. Mineralized zones west of the pit were encountered in drill holes by Weaco Exploration Ltd. in 1991 (Appendix 11.1). Chemical assays of recent production from the open pit are given in Table 3.3. Assays of drill hole samples from holes drilled by the U.S. Bureau of Mines are in Table 3.4. The geochemistry of the deposit is discussed in section 4.4.2.

3.3.2 Center mine

The Center mine occurs along the Carlisle fault in sec. 1, 12, T2S, R21W at an elevation of 1642 m (collar of shaft). The mine consists of a shaft and a decline (Map 4).

As ore shoots were not exposed at the surface, production did not occur until 1937. The Center mine was found when miners drifted from the adjacent Pennsylvania mine on the 37-m level. In 1941, a raise was driven to the surface which subsequently became the Center shaft. From 1944 to 1946, the Carlisle Development Co. sank the shaft to 91 m and developed about 914 m of drifts. Four levels were developed at 37, 46, 76, and 91 m. Production during this period is summarized in Table 3.5.

Various operators controlled the Center mine from 1942 to 1975, but little development occurred. In 1975, Dresser Industries Corp. began minor production, ----development, and core drilling (Hedlund, 1990b). In 1985, Mt. Royal Mining and Exploration Co. acquired the Center mine and in 1987 leased it to R and B Mining Co., who drove a decline below the old Center shaft and began production (Fig. 3.7). R and B Mining Co. is currently producing and shipping the ore to ASARCO, El Paso, Texas. R and B Mining Co. drilled underground and descriptions of drill core are in Appendix 11.1. The Center decline is at an elevation of 1615 m and extends to about 122 m below the surface.

The Center deposit consists of a breccia zone up to 24 m wide along the Carlisle fault. The host rocks consist of altered purple to green andesite porphyry flows of the Summit Mountain formation and purple to green to white tuffs, sandstones and volcanic breccias. Ore consists of gold, electrum, silver minerals, sphalerite, galena, and chalcopyrite in a gangue of

quartz, pyrite, chlorite, iron oxides, adularia, gypsum, calcite, illite, siderite, dolomite, and clay minerals. Ore shoots are 0.3-1.8 m thick and occur in bends and splays of the Carlisle fault. Fault and vein orientations of each level were plotted on stereonets, however no structural trends with depth were observed. All orientations are shown in Figure 2.21. Two holes were drilled by the U.S. Bureau of Mines in 1941; assays are in Table 3.6 (Griggs and Wagner, 1966; Russell, 1947). Dresser Minerals also drilled at the Center mine (Appendix 11.1; Maps 5, 6). The chemistry of ore shipments is discussed in section 4.4.1.

3.3.3 Pennsylvania mine

The Pennsylvania mine was one of the first claims filed in the district in 1881. It is located east of the Carlisle and Center mines on the west-northwest-trending Carlisle fault in sec. 1, 12, T17S, R20W (elevation 1640 m). Development consists of three inclined shafts to approximately 37 m depth with 70° dip south. A short adit and several cuts also occur at the surface. The mine connects with the Center mine on the 37-m level, but the underground workings are extremely hazardous (Map 4).

The Pennsylvania mine consists of a breccia zone up to 24 m wide. The host rocks consist of andesite and sandstones of the Summit Mountain formation and younger ash-flow tuff. The Blue Goose fault intersects the Carlisle fault at the Pennsylvania mine (Map 1, 2). Ore is concentrated at inflections within the Carlisle fault zone produced by the Blue Goose fault. Ore consists of gold, silver minerals, sphalerite, galena and chalcopyrite and is similar to ore at the Center and Carlisle mines. Two drill holes were driven at the Pennsylvania by the U.S. Bureau of Mines which did not indicate any additional ore (Appendix 11.1; Griggs and Wagner, 1966). A series of samples were collected and assayed, probably in the early 1900s (Table 3.7). Two samples were collected for this study and assayed, but did not contain gold or silver (P1, P2, Appendix 11.6).

.

.

3.3.4 Ontario mine

The Ontario mine is located along the Carlisle fault east of the Pennsylvania shaft in sec. 7, T17S, R20W (elevation 1600 m) and consists of an inclined shaft (70°S dip) and one short adit (27 m long) intersecting the 12-m level. The shaft is 49 m deep with levels at 12, 30, and 43 m. R and B Mining Co. drove a second adit (9 m long) west of the shaft in 1988 in hope of intersecting the Pennsylvania workings (Map 5). Although sulfide ore was found, it was too high in fluorine and too low in gold to be economical. Several pits and shallow shafts also expose the vein along strike.

Production from the Ontario mine is minor and amounts to less than 1500 tons of ore averaging 0.24 oz/ton (8 ppm) Au and 13.6 oz/ton (466 ppm) Ag. The mine produced in 1941, 1942, 1945, and 1949.

The Carlisle fault strikes east-west and dips 70°S at the Ontario mine (Map 1, 2). The host rocks consist of sandstones and andesite porphyry of the Summit Mountain formation. The vein is about 0.3 m wide on the 12-m level, but widens to about 1.5 m in the R and B. Mining Co. adit to the west. Sampling of the 30- and 43-m levels by J. D. Lowell in 1971 ranged from 0.003 to 0.485 oz/ton (0.1-17 ppm) Au, 0.54 to 23.94 oz/ton (18-820 ppm) Ag, and 0.19 to 0.46% Cu, but mineralized zones were small and spotty (J. D. Lowell, unpubl. report, 5/28/71). A sample from the ore zone collected in 1966 assayed 0.01 oz/ton (0.3 ppm) Au, trace Ag, 0.10% Cu, 0.10% Pb, and 0.20% Zn (Shattuck Denn Mining Corp., unpubl. report, 3/10/66). Sampling for this report detected no significant gold or silver, although one sample assayed 0.3 oz/ton (10 ppm) Ag (#ONTARIO, Appendix 11.6). Copper values ranged from 40 to 12,700 pm; lead values ranged from 30 to 29,200 ppm; and zinc values ranged from 18 to 46,800 ppm (#328a, b, c; 340a, b, c, O-1, ONTARIO, Appendix 11.6). All of the samples contained quartz and illite. Adularia, calcite, and sphalerite are common in some samples. Samples enriched in base metals contained galena, chalcopyrite, and sphalerite and sample #ONTARIO (dump sample) contained nantokite (CuCl). Acid-sulfate alteration occurs at the Ontario shaft and is discussed in section 5.

3.4 Description of gold-silver mines

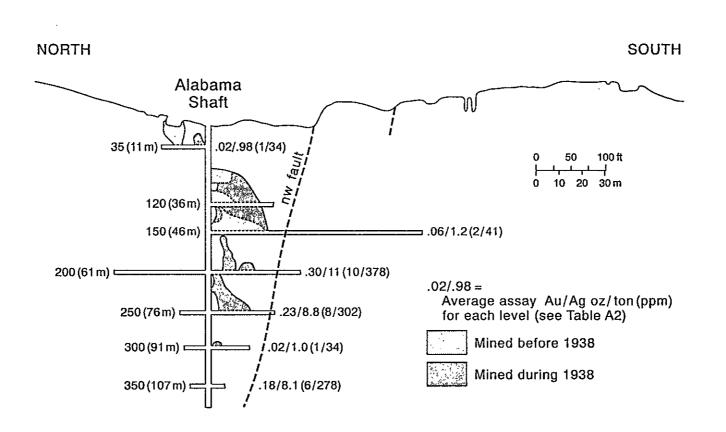

3.4.1 Alabama and Homestake mines

The Alabama and Homestake mines occur along the north-trending Alabama fault in sec. 14, T17S, R21W. The Alabama mine is at an elevation of 1580 m (collar of shaft). The Homestake mine is at an elevation of approximately 1603 m (Map 1, 2).

The Alabama group of claims consist of nine patented claims which were patented on October 2, 1915 by the Torreroca Mining Co. (mineral survey #1624). The Homestake No. 1 was patented on October 18, 1904 (patent #39753, mineral survey #1448) by the Dixie Gold Mining and Reduction Co.

Several shallow pits and shafts comprise the Alabama-Homestake groups. The Alabama mine consists of a 1½ compartment shaft with eight levels at depths of 11, 24, 34, 46, 61, 76, 91, and 107 m below the shaft collar (Fig. 3.8). The 46- and 61-m levels are the most extensive and are 61-91 m long. The shaft dips 80°W and is 113 m deep. The underground workings are flooded to the 11-m level and are currently inaccessible. Two holes were drilled in 1991 by Great lakes Exploration Inc.; a summary of the drill data is in Appendix 11.1. Locations and summary of geochemical analyses are in Figure 4.27.

The Homestake mine consists of several shallow pits, a few short adits and a 40-m shaft. The shaft consists of two levels at depths of 20 and 35 m. Early production occurred from the Alabama in the late 1800s (Engineering Mining Journal, 3/30/1895, p. 302), but total production prior to 1908 is unknown. In 1908, less than 1000 tons of ore was shipped by the Torreroca Mining Co. (NMBMMR files). By 1910, the Alabama shaft was at a depth of 113 m and development began on all levels (F. W. Smith, unpubl. report, 8/5/1910). In the 1930s, development of the mines resumed and the mine produced from 1936 to 1938. In June 1938, George Utter produced 1038 tons of ore averaging 0.32 oz/ton (11 ppm) Au and 14 oz/ton (480 ppm) Ag (H. Schmidt, unpubl. report, 7/18/53). The mine closed in 1939 and remained idle until 1950 when L. H. Foster mined 1526 tons of ore averaging 0.31 oz/ton (11 ppm) Au and 14.3 oz/ton (487 ppm) Ag (Table 3.8; ASARCO, El Paso smelter return

.

receipts, 1950-1951). Total production is estimated at about 4000 tons of ore averaging 0.3 oz/ton (10 ppm) Au, 13 oz/ton (446 ppm) Ag, and 0.03% Cu. In July 1991, Great Lakes Exploration Co. began a surface sampling and drilling program at the Alabama to evaluate the economic potential. Additional drilling is recommended by this author. Ore was produced from the Homestake mine in 1936, 1938, 1939, and 1941; however, less than 500 tons of ore averaging 0.23 oz/ton (8 ppm) Au and 5.8 oz/ton (199 ppm) Ag was shipped (NMBMMR files).

The Alabama orebody occurs along the north-trending Alabama fault in a silicified hematite-rhyolite breccia. Fragments of andesite, rhyolite, and vein quartz are cemented by-silicified hematite. The breccia zone occurs along the fault with a strike of N10°E and dips 80°W. The zone is about 2-3 m wide at the Alabama shaft and varies along strike between 1.2 and 6.1 m in width. The ore zone averages 1-2 m wide but varies from 1.2 to 1.8 m in width. Some ore shoots were up to 18 m long (H. Schmidt, unpubl. report, 8/18/53). Early reports state that ore averaged 1 oz/ton (34 ppm) Au and 20 oz/ton (186 ppm) Ag (Engineering Mining Journal, 3/16/1895, p. 302).

The host rocks consist of the younger ash-flow tuff overlain by the porphyritic andesite of the Dark Thunder Canyon formation. Rhyolite dikes and plugs have intruded along the Alabama fault (Fig. 2.18; McLemore and Quigley, 1992).

The ore at the Alabama and Homestake mines consists of gold and silver, with trace amounts of galena, sphalerite, and chalcopyrite in a gangue of quartz, hematite, pyrite, sericite, and mixed-layer chlorite/smectite. Visible gold or electrum is locally found (T. Quigley, pers. comm. August 1991). Seams of calcite, 1 mm or less wide, cut the ore and altered rocks and were reported to be associated with zones assaying low gold values (George Utter, unpubl. report, 1938). Averages of gold and silver assays from each level of the Alabama mine suggest an increase in gold and silver with increase in depth (Table 3.9; Fig. 3.8).

A northwest crossfault (strike N70°W, dip 70°N; Fig. 2.18) offsets the Alabama fault

south of the Alabama shaft. Subsurface mine maps indicate that this fault also offsets the orebody (F. W. Smith, unpubl. report, 8/5/10). Additional faults occur in the vicinity (Map 2, Figs. 2.18, 3.8) but the offset in mineralization is unknown.

3.4.2 Jim Crow-Imperial-Gold King mines

The Jim Crow, Imperial, and Gold King mines occur along various north and northwest-trending faults in sec. 14, T17S, R21W. Eight patented claims make up this group (Imperial, Jim Crow, Gold King, Tunnel, Gold Bug, Red Prince, Three Brothers, and Contention) which were patented on July 11, 1899 by the Steeple Rock Development Co. (mineral survey #1012A-H, patent #31323).

Most of the development work was completed prior to patenting in 1899. However, early records of the mining claims were lost during the San Francisco earthquake in 1906, so very little concerning the early history is known. In 1914, George Utter purchased the group of claims. He continued development and production. Two diamond drill holes were drilled prior to 1936. Sludge samples had assays ranging from 0.03 to 0.04 oz/ton (1 ppm) Au and 4.05 to 7.08 oz/ton (139-243 ppm) Ag. By 1941, development consisted of two 61-m shafts (Jim Crow and Imperial), four 30-m shafts, and at least ten additional shafts ranging in depths from 3 to 18 m. Several adits, crosscuts, trenches, and pits also expose the veins. In 1967, McFarland and Hullinger conducted a percussion drilling program near the Imperial shaft, but results are unknown. In 1969, Grant County Mining Co. leased the property and made one ore shipment. In 1977, Oak Creek Contracting, Inc. obtained the property and in 1981 entered a joint venture agreement with Queenstake Resources, Ltd. (Fig. 3.9).

Production prior to 1912 is largely unknown due to loss of most of the early records, but at least 429.9 tons of ore averaging 0.82 oz/ton (28 ppm) Au and 38.3 oz/ton (1310 ppm) Ag were produced (L. Utter, unpubl. report, 6/19/36). Production from 1912 to 1969 was sporadic (1915-1917, 1920, 1932, 1936-1938, 1940, 1969) and amounted to 1341 tons of ore averaging 0.31 oz/ton (11 ppm) Au and 13.9 oz/ton (477 ppm) Ag. Most of this production

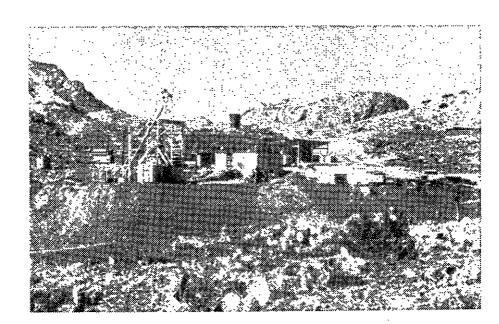

Figure 3.9-View of Imperial mine in 1984.

.

(1915-1938) was by George Utter. Oak Creek Contracting, Inc. produced 5035.1 tons of ore averaging 0.074 oz/ton (3 ppm) Au and 3.33 oz/ton (114 ppm) Ag from 1980 to 1984 (Queenstake Resources Ltd., unpubl. report, 1987). Total production is estimated as 6806 tons of ore averaging 0.17 oz/ton (6 ppm) Au and 7.6 oz/ton (261 ppm) Ag (Table 3.10). Copper, if present, rarely exceeded 0.4% Cu. Chemical analyses of some ore shipments are listed in Table 3.11. A summary of drill data is in Appendix 11.1.

Ore from this group of claims occurs along several northwest-trending faults (Maps 1, 2). The host rocks consist of younger ash-flow tuff interbedded within the porphyritic andesite of the Dark Thunder Canyon formation (Fig. 2.7). Several minor faults split off of the main fault and many are mineralized. Underground, several post-mineralization faults cut and offset the orebodies (Queenstake Resources Ltd., unpubl. report, April 1982). The ore occurs in silicified hematite breccia, similar to ore at the Alabama and Homestake mines. Veins vary in width from 0.6 m to 12 m and dip steeply to the west or southwest 60-80°. The breccia zone consists of fragments of rhyolite, and esite, and vein quartz all cemented by silica and iron oxides. Locally small breccia fragments of high grade ore (1 m diameter) occur in the veins. Ore minerals include native gold, native silver, galena, sphalerite, chalcopyrite, covellite, and bornite in a gangue of quartz, sericite, pyrite, chlorite, calcite, feldspar, and hematite (personal examination of drill core and Queenstake Resources Ltd., unpubl. report, April 1982). Sulfide minerals, except for pyrite, are extremely small (<100 microns). Mottramite ((Cu,Zn)Pb(VO_4)(OH)) is a common alteration product associated with the sulfides. It is reported that the upper portions of the Imperial orebody contained more gold than silver (Lindgren et al., 1910) grading at depth to more silver than gold. Base-metal sulfides appear to increase with depth. Hedlund (1990a) reports a chemical analysis of a sample from the Jim Crow mine that contained 100 ppm Mo. Queenstake Resources Ltd. reports reserves of 155,535 tons of ore averaging 0.11 oz/ton (4 ppm) Au and 3.45 oz/ton (118 ppm) Ag from the property (Queenstake Resources Ltd., unpubl. report, 1987).

3.4.3 Mt. Royal mine

The Mt. Royal mine lies on the Imperial fault in sec. 23, T17S, R21W at an approximate elevation of 1463 m. The eight claims which make up this group are the Golden Fleece Nos. 1, 2, and 3, Ruby Quartz, Imperial Extension, South Jim Crow, Prince Imperial, and Prince Imperial Extension, which were patented on October 10, 1922 (mineral survey #1712, patent #881743). The mine consists of a 99-m shaft with levels at 30, 61, and 99 m. The shaft is inclined with a dip of 85°W (Fig. 3.10).

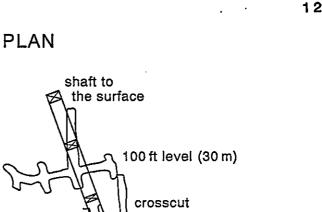

The Mt. Royal mine was first developed in the early 1900s, but early production, if any, is unknown. The first known reported production was in 1939-1941 by E. T. Richards. George Utter acquired the mine in 1941 and also shipped ore. In 1970-71 and 1981, Charles and Douglas Hanson produced additional ore. Total known production amounts to 2452 tons of ore averaging 0.12 oz/ton (4 ppm) Au and 3 oz/ton (103 ppm) Ag. Chemical analyses of some partial ore shipments are in Table 3.12.

The Mt. Royal deposit is an extension of the Jim Crow-Imperial deposit and is fault controlled. Early reports describe narrow streaks of gold within a hematite breccia that were mined out. Two subparallel veins occur at the mine (Fig. 3.10), the Mt. Royal and Jim Crow-Imperial veins. A zone of chloritic-altered porphyritic andesite separates the two veins (H. W. Evans, unpubl. report, 1/20/17). No samples were collected for this report.

3.4.4 Laura mine

The Laura mine is located in Laura Canyon, east of Vanderbilt Peak (Laura Mountain on some maps) in sec. 2, T17S, R21W. The main shaft is at an approximation elevation of 1707 m. In the late 1880s, a Chinese cook discovered the Laura deposit and sank a 20-m shaft. Two claims, the Laura and Clara, were subsequently patented on May 14, 1901 by Jesse Wasserman (mineral survey #1067). The two patented claims comprise 35.92 acres.

The main shaft is 196 m deep (Richter and Lawrence, 1983) and dips 80-85°W. Two additional shafts access the lower workings which consists of six levels and several sublevels.

`

.

The five upper levels are at depths of 15, 41, 59, 87, and 113 m. The second and third levels are the most extensive and are about 122-152 m long (Fig. 3.11). Several pits and open-cuts expose the vein at the surface.

The Laura mine was first worked in the late 1860s when approximately 1800 tons of ore averaging 1.2 oz/ton (58 ppm) Au and 15 oz/ton (514 ppm) Ag were produced (C. M. Autremict, unpubl. report, 3/10/39). The Twin Peaks Mining and Milling Co. produced approximately 3600 tons of ore grading 1.07 oz/ton (37 ppm) Au and 14.21 oz/ton (487 ppm) Ag from the first and second levels from 1907 to 1909. The Laura mine closed in 1909 but was reopened in 1937 by W. O. Wills, Jr. After sinking the shaft to 70 m, Wills produced · 2,229 tons of ore with a grade of 0.4 oz/ton (14 ppm) Au and 13 oz/ton (446 ppm) Ag in 1938. The Wilmont Mining Co. acquired the mine and developed the shaft to at least 152 m. From 1939 to 1942, Wilmont Mining Co. produced 5000-6000 tons of ore averaging less than 0.2 oz/ton (7 ppm) Au and 12 oz/ton (411 ppm) Ag. Some copper and lead were also produced. The mine closed again in 1942. In July 1977, Charles and Douglas Hanson acquired the lease to the Laura mine. In 1982, the Hansons produced about 1000 tons of ore averaging 0.06-0.09 oz/ton (2-3 ppm) Au and 3-6 oz/ton (103-206 ppm) Ag (Douglas Hanson, pers. comm. December 1991). Some copper (0.03-0.05%) and lead (0.06%) were also produced. Production is summarized in Table 3.13.

The Laura mine occurs near the junction of several converging northwest-trending faults that make up the Laura fault, and the west-northwest-trending Carlisle fault (Map 1, 2). A rhyolite dike, 6-15 m wide, has been intruded within the Laura fault zone south of the shaft. The Laura fault zone separates andesite porphyry of the Summit Mountain formation to the northeast from basaltic andesite of the Dark Thunder formation (Map 1). Brecciated andesite, basaltic andesite, and rhyolite fragments comprise the fault zone and are cemented by at least two generations of quartz.

The vein is about 3 m wide near the shaft and dips 62°SW. Unpublished reports describe the presence of two veins in the inaccessible workings. The "pay ore shoot" is west

.

of the shaft and has been mined to at least the fifth level. This shoot is 0.3-6 m wide and intersects the larger vein (6-8 m wide) at slightly below the sixth level east of the shaft. Both veins consist of gold and silver with some fine-grained galena and chalcopyrite with a gangue of quartz and pyrite. Early reports state that the ore consisted of argentite, cerargyrite, pyrargyrite, and gold (Engineering Mining Journal, 10/26/1907, p. 805).

Sampling of surface outcrops for this report indicated sporadic assays; however, one sample assayed 0.12 oz/ton (4 ppm) Au and 11.2 oz/ton (384 ppm) Ag (#246; Map 2; Appendix 11.6). The sample consisted predominantly of quartz with minor amounts of feldspar, anatase, and illite. Sampling of underground exposures in 1982 by Phelps Dodge - Corp. yielded assay results similar to production values from the various levels (Table 3.14). These assay data suggest that silver and gold assays decrease with depth, but this observation should be tested further by drilling. Chemical analyses of ore shipments are in Table 3.15.

3.4.5 Blue Goose and Goldenrod mines

The Blue Goose and Goldenrod mines lie along the northwest-trending Blue Goose fault in sec. 7, T17S, R20W. No production has been reported from either mine. The Blue Goose mine consists of a caved shaft surrounded by a mine waste dump and is probably less than 30 m deep. The Goldenrod mine consists of a 44-m adit, trending S56°E. Numerous prospect pits and shallow shafts expose the vein along strike between the Blue Goose mine (south of the Center shaft) and the Goldenrod mine (south of the Blue Goose mine; Maps 1, 2). The host rocks are sandstone and andesite porphyry of the Summit Mountain formation and the mineralization is fault controlled.

At the Blue Goose mine, dump samples contain quartz, clay minerals, and pyrite. A sample southeast of the mine consisted of quartz, chlorite, and pyrite and assays did not contain any gold, but did assay 0.54 oz/ton (19 ppm) Ag, 734 ppm Cu, 54 ppm Pb, and 482 ppm Zn (#148, Appendix 11.6). The vein is well exposed in the pit and strikes N52°W with a dip of 74°SW, but is less than a meter wide.

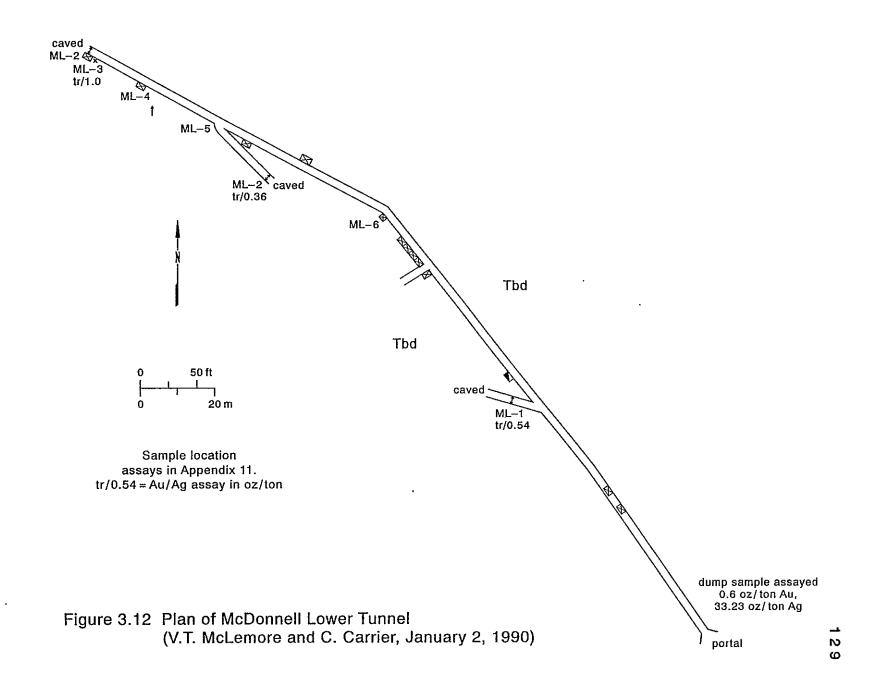

A 3-m chip sample collected across the back at the portal of the Goldenrod adit revealed no gold or silver and low values of copper, lead, and zinc (#60, Appendix 11.6). However, a 0.6-m chip sample across the face at the end of the adit, while it showed no gold, it did assay 0.22 oz/ton (8 ppm) Ag, 1200 ppm Cu, 5600 ppm Pb, and 5300 ppm Zn (#GOLDENROD, Appendix 11.6). The sample consisted of quartz, feldspar, chlorite, pyrite, titanite (sphene), and hedenbergite (Appendix 11.3). The vein exposed at the face is a silicified breccia cut by white quartz veins. The host rock (andesite porphyry) has been silicified and altered to chlorite.

Three additional samples were collected south of the Goldenrod adit and assayed. Only one sample contained detectable gold: 0.001 oz/ton (0.03 ppm) Au (#922; Appendix 11.6). Assays of samples ranged from 1.94 to 3.18 oz/ton (67-109 ppm) Ag, 2800 to 14,900 ppm Cu, 894 to 45,000 ppm Pb, and 235 to 1600 ppm Zn (#911, 923, 927; Appendix 11.6). The samples consisted of quartz, feldspar, kaolinite, and chlorite; one sample (#922) also consisted of trace amounts of cerusite, anhydrite, and brookite (Appendix 11.3).

3.4.6 East Camp group of mines

For the purpose of this study, the East Camp group of mines includes mines and prospects along the southeastern portion of the East Camp-Summit fault in sections 3, 6, 7, 8, 9, and 16, T17S, R20W. It includes eight patented claims (Table 3.1), numerous unpatented claims, and state land. Larger mines include Nugget, East Camp, McDonald (Fig. 3.12), Davenport, and Thanksgiving.

Development along the East Camp vein began in the late 1800s. Greatest production occurred from 1933 to 1942 when the East Camp mines were the largest producers. Development along the East Camp vein is the most extensive in the district (Fig. 3.13), but the entrances to most of the underground workings are caved and hazardous. The vein is mineralized for over 1372 m along strike from the Nugget southeastward to the Thanksgiving (Map 2). Numerous adits, stopes, drifts, and shafts (up to 193.5 m deep) are developed along

Mine	Years of production	Tons of ore	Au oz/ton	Ag
oz/ton		(ppm) (ppm)		
East Camp	prior to 1987	88,115.5	0.293 (10.0)	21.89 (750)

National Bank	1936-1937	100	0.24 (8)	17.85 (612)

Table 3.16—Known production from the East Camp and Summit groups of mines (from various unpublished reports). These production statistics probably represent minimum production totals.

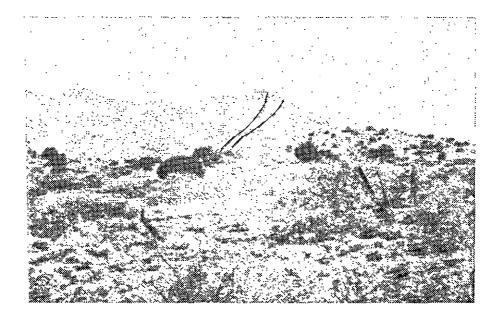

Figure 3.13-View of East Camp-Summit fault, looking northwest at the Summit Mountains.

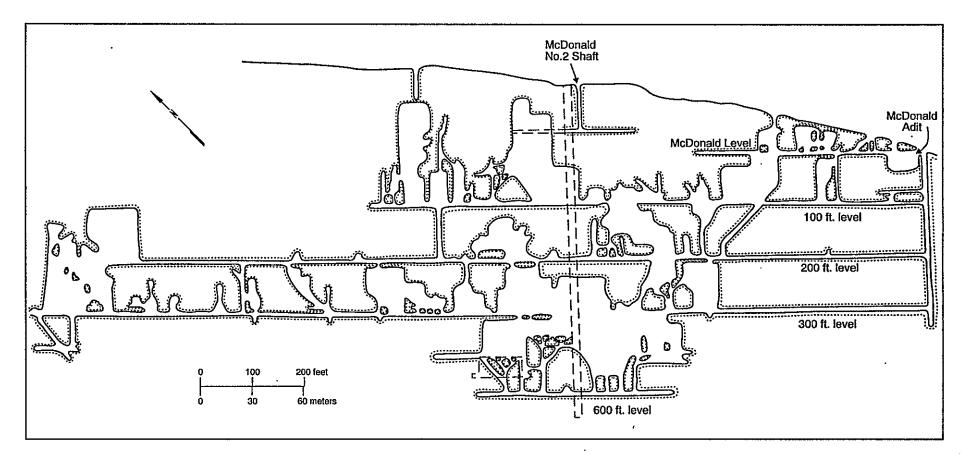

Figure 3.14 Longitudinal section through McDonald Mine, East Camp vein, Steeple Rock District (Gillerman, 1964).

the vein (Fig. 3.14). Known production amounts to 105,744.5 tons of ore averaging 0.303 oz/ton (10.4 ppm) Au and 22.3 oz/ton (765 ppm) Ag.

Little is known concerning the history and production of the various mines. Some records were lost in the San Francisco earthquake. Numerous companies have examined the property and a few companies drilled, but these data are unavailable.

The East Camp vein occurs along the East Camp fault which strikes N70°W and dips steeply to the northeast and locally to the southwest (Maps 1, 2). Host rocks are andesite and sedimentary rocks of the Dark Thunder Canyon and Summit Mountain formations. The vein varies in width but averages 2 m. Some ore shoots are 4.6-6.1 m wide. The veins are sinuous, pinch and swell along strike, and have complex textures, including comb, cockade, crustification, and drusy quartz. At least three periods of brecciation and recementation have occurred. Precious-metal values are low at the surface (Appendix 11.5, Map 2), but increase with depth. Some ore shoots may continue below the deepest level of workings. Small faults intersect the East Camp fault and appear to localize ore. Alteration includes argillic, propylitic, and silicification. Chemical analyses of some ore shipments from the East Camp mine are in Table 3.17.

3.4.7 Summit group of mines

For the purpose of this study, the Summit group of mines includes the mines and prospects along the Summit vein in sections 25 and 26, T16S, R21W, from the Angello windmill (north of Telephone Ridge) northwestward to, and including, the National Bank (Bank, Smith) mine (Maps 1, 2). This group consists of ten patented claims (Table 3.1) and numerous unpatented claims. Biron Bay Resources, Ltd. currently controls the property.

Little is known about the early history of the Summit mines. The patented claims were

most likely filed near the turn of the century. By 1920, the Summit adit was 148.4 m long and the Apex was 62.5 m long. Several shafts (up to 80 m deep) and prospect pits also developed the vein prior to 1920 (George H. Utter, unpubl. report, May 6, 1920). There was some production in 1895, but total figures are not known. At least \$25,000 worth of gold and silver was produced from these mines from 1895-1920 (George H. Utter, unpubl. report, May 6, 1920).

The National Bank (Bank) mine operated in 1895 when the two Smith brothers sank the shaft to 61 m. A mill was built before 1900, but the mine and mill closed in 1900 and production is unknown. The Bank reopened in 1936-1937 when 100 tons of ore averaging 0.24 oz/ton (8 ppm) Au and 17.85 oz/ton (612 ppm) Ag were produced (Table 3.16). The Bank is now 60.8 m deep with levels of 22.9 m, 30.5 m, 45.7 m, and 61 m.

By 1964, the Apex adit was 91 m long and the Summit adit was 152 m long (Gillerman, 1964). In 1977, Summit Minerals, Inc. (Charles and Douglas Hanson) was formed and controlled the Summit group of mines. Several companies have examined the property over the years. The adits now connect (Fig. 3.16).

In 1982-1984, Inspiration Mines Inc. examined and drilled along the Summit vein (Fig. 3.16). Fifteen holes were drilled (Appendix 11.1). Reserves were calculated as 1,100,000 tons in three separate ore shoots above the 1615-m level (91.4 m below the Summit adit level) with combined grades of 0.062 oz/ton (2.1 ppm) Au and 4.57 oz/ton (157 ppm) Ag. Part of one orebody contained 207,400 tons of ore grading 0.076 oz/ton (2.6 ppm) Au and 7.76 oz/ton (266 ppm) Ag. Inspiration Minerals Inc. defined five additional ore shoots 121.9 m below the Summit adit level that contained 121,500 tons grading 0.079 oz/ton Ag. It is unknown how much, if any, of these reserves have been subsequently mined. These reserves occur over a strike length of over 480 m and averages 2 m thick with lower grades of ore surrounding the higher grade deposits. Two or more veins are locally present (Watts, Griffits, and McQuat, Inc., unpubl. report, February 12, 1988).

In 1988, Nova Gold Resources Inc. began exploration of the Summit mine area. Biron

.

Figure 3.16. Map of Summit and Apex Mines, Summit vein. Modified from unpublished maps by V.T. McLemore and J.M. McLemore.

- 13 5 Bay Resources, Ltd. became a partner in 1989 and up to 120 drill holes have been drilled since 1988 (Appendix 11.1). Reserves are estimated as 1,450,000 tons of ore averaging 0.179 oz/ton (6.1 ppm) Au and 10.26 oz/ton (352 ppm) Ag (Petroleum and Mining Review, v. 14, 1992, p. 2). Total production from these mines is unknown, although known production is 74,050 tons of ore averaging 0.13 oz/ton (4 ppm) Au and 5.54 oz/ton (190 ppm) Ag (Table 3.16).

The Summit vein lies along the East Camp-Summit fault which strikes N40°W and dips 70-85° northeast. Host rocks are andesite and dacites of the Summit Mountain formation. Sericite and chlorite occur along the Summit vein with erratic but strong silicification. Acid-sulfate alteration occurs east of the Summit mine and at the Bank mine. The vein ranges in width from 6.0 to 30.5 m. Prominent quartz and quartz-calcite veins crop out (Fig. 2.15). Calcite is more abundant near the top and decreases with depth, but is still present at depth in drill cores (Appendix 11.1). Trace base-metal sulfides occur at depth. The vein consists predominantly of quartz which is generally brecciated and recemented. Comb, cockade, lattice, and drusy quartz are common. Large blocks of sericitized and silicified country rock are common in the vein. Manganese and iron oxides are locally abundant. Other gangue minerals include illite/sericite, chlorite, adularia, pyrite, kaolinite, and smectite (Appendix 11.3). Gold occurs as native gold, electrum, and is also associated with pyrite. Silver occurs as electrum, argentojarosite, tetrahedrite and similar sulfosalts, and is associated with iron and manganese oxides, and native silver (W. Baum, unpubl. report, March 31, 1988). Acanthite is probably also present. High gold and silver assays are locally associated with motramite or mimettite.

In 1921, sampling of the Summit and Apex mines occurred. Assays of 28 samples from the Summit adit averaged 0.0755 oz/ton (2.6 ppm) Au and 4.03 oz/ton (138 ppm) Ag. An average of 24 samples from the Apex adit was 0.0525 oz/ton (1.8 ppm) Au and 3.33 oz/ton (114 ppm) Ag (J. Daniell, unpubl. report, February 18, 1934). The higher values are in the center of the vein. Assays at the surface taken for this study are typically low (Map 2,

136

Appendix 11.5). However, one sample from the Bank mine contained 0.04 oz/ton Au, 0.44 oz/ton Ag, 1.51 ppm Hg, and 160 ppm Mo (#BA, Appendix 11.5). Ore shipments in the 1980s were rejected by the smelters because they contained too much calcium carbonate.

3.4.8 Norman King, Billali, and Hoover mines

The Norman King, Billali, and Hoover mines occur along the Norman King-Billali fault in sec. 26 T16S R21 W. The area consists of numerous pits, adits, and shafts (Map 2). The deepest is the Norman King mine, 152 m deep. A plan of the Hoover and Billali adits is in Figure 3.17. Total production from these mines since 1919 amounts to 4,120 tons grading 0.19 oz/ton (6.5 ppm) Au and 12 oz/ton (411 ppm) Ag (Table 3.18). Production, if any, prior to 1919 is unknown. Gillerman (1964) reports much higher production figures because he reported the figures in tons when actually his figures should be in pounds of ore produced (confirmed by this author from two separate unpublished sources). Another common mistake in the literature is the mislocation of the Billali mine. The Billali mine is south of the Norman King, even though some maps place it to the north where the Mohawk mine is. Also, different spellings of Billali occur; the most common in unpublished sources is used here.

The Norman King mine was originally located as the Norman mine in 1883 by B. V. Steed and F. L. Heft. A patent plat was prepared in 1885 (mineral survey #515), but the patent application was never completed. Not much development occurred until the late 1800s when Herbert Hoover worked in the area as a mining engineer. The Hoover Tunnel (also known as the Knutson adit) is named for him. The Norman claim was relocated as the Norman King mine in 1900 by O. V. Ward. The Billali claim was also staked in the 1880s.

The Norman King-Billali fault strikes northwest, dips 70°NE, and consists of a series of quartz veins that bifurcate and pinch and swell along strike. The entire zone is several tens of meters thick and consists of silicified country rock, quartz, some calcite, rare fluorite, pyrite, and traces of thin streaks of microscopic sulfides (galena, sphalerite, chalcopyrite). Bladed calcite (lattice texture) is present locally but in concentrations much less than found at

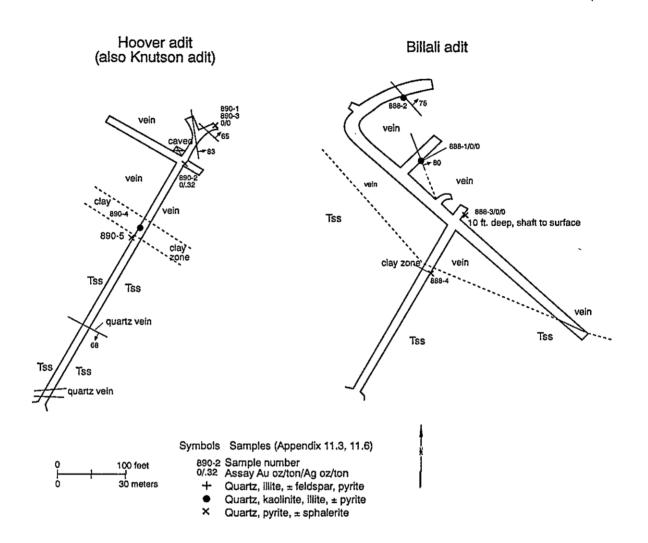

Figure 3.17 Plan maps of Hoover and Billali adits (V.T. McLemore and J.M. McLemore, brunton, pace and surveys, 6/8/92).

•

the Summit mine. Fluorite veins are prevalent at the Mohawk but fluorite concentrations decrease southeastward, and only trace amounts of fluorite are found at the Billali mine. Fluorite is absent in drill core of holes beneath these zones. Two deep drill holes (M91-3, M91-4; Appendix 11.1) consist of deep intervals below the veins of silicified porphyritic andesite containing disseminated galena, sphalerite, chalcopyrite, and pyrite. The sulfides have replaced feldspar phenocrysts. Host rocks are andesites of the Summit Mountain formation. Alteration includes sericitic, chloritic, and silicification.

Very few data are available on the chemistry of the Norman King-Billali fault. Gold and silver assays are sporadic, production grades range from 0 to 8.4 oz/ton (0-288 ppm) Au and 3 to 433 oz/ton (103-14,846 ppm) Ag. The higher grade shipments were most likely hand-sorted ore. Copper content rarely exceeds 0.3% and lead content is also low (less than 0.005%). Silica is typically high (76-87% SiO₂). Hedlund (1990b) reports a semiquantitative spectrographic analyses of a sample from the Norman King that contained 100 ppm Ag, 100 ppm Ba, 150 ppm Cd, 5,000 ppm Cu, 20,000 ppm Pb, and 50,000 ppm Zn. Samples collected for this report (888, 889, and 890, Appendix 11.6) are low: no gold, 0-0.57 oz/ton (0-20 ppm) Ag, and up to 373 ppm Pb. Drilling by Biron Bay Resources, Ltd. has detected mineralized zones, and an ore shoot has been discovered with inferred reserves of 219,000 tons averaging 0.244 oz/ton (8.4 ppm) Au and 12.8 oz/ton (439 ppm) Ag (Petroleum and Mining Review, v. 14, 1992, p. 2). A second mineralized zone was also discovered, but reserves have not been announced.

3.4.9 Twin Peaks mines

8. 2 1

> The Twin Peaks mines lie north of the map area, north of Twin Peaks in sec. 8, T16S, R21W (Fig. 2.7). The deposit was discovered in the late 1880s. Development consists of five caved and inaccessible shafts: Discovery (87 m deep), Free Gold (282 m deep), Ethel (46 m deep with levels at 17 and 30 m), New Strike and Rival (probably less than 15 m or so). In 1973, Minerals Economic Corp. and Fraser-Martin Mines, Inc. core drilled about 610

140

m, however the results are unknown.

Production statistics are ambiguous. Briggs (1982) reports total production from the Mayflower-Commerce, Copper Basin, Twin Peaks, and possibly Fraser mines as 1000 tons of ore yielding 1,115 oz Au, 3,640 Ag, and 1,965 lbs Cu. However, Keith et al. (1983) reports total production from a Twin Peaks district in Arizona (which may include part of New Mexico) as 2000 tons of ore yielding 500 oz Au, 10,500 oz Ag, 15,000 lbs Cu, and 17,000 lbs Pb. Very few, if any, mines in the Arizona portion of the Steeple Rock district could yield such production as reported by Keith et al. (1983). Most likely, much of the production reported by Keith et al. (1983) includes production from Twin Peaks and possibly the Fraser mines, but the actual breakdown of production is unknown.

The Twin Peaks mines occur along a north- to northeast-trending fault in andesite of Dark Thunder Canyon. The fault is poorly exposed at the surface, but unpublished reports state that it strikes N46°E and dips 80-85°northeast. Numerous bends and splays of the fault act as ore-concentrators. The fault, where exposed in shallow pits and trenches at the surface, is 2-3 m wide and reportedly widens at depth to 6-15 m. The oxidized zone occurs above the 79-m level and sulfides below 79 m (J. F. Fraser, unpubl. report, 9/24/59). The vein consists of quartz, illite, feldspar, pyrite, chlorite, and iron oxides. Wahl (1980) reports that native wire gold occurs in hematite stringers at the Twin Peaks mines. Assay of a sample from the Discovery mine reportedly contained 6 oz/ton (206 ppm) Au and 60 oz/ton (2,057 ppm) Ag (Carl Boderick, pers. comm. 9/5/92). A chip sample across the vein (1 m wide) collected and assayed for this study contained 0.1 oz/ton (3 ppm) Au, 2.28 oz/ton (78 ppm) Ag, 110 ppm Cu, 110 ppm Pb, and 95 ppm Zn (#1086A, Appendix 11.6). Briggs (1982) reports two assays of tr-0.03 oz/ton (1 ppm) Au and 0.8 oz/ton (27 ppm) Ag with low copper, lead, and zinc values (less than 100 ppm).

Alteration at the Twin Peaks mines is weak and poorly exposed except in shallow pits. Examination of dump material and exposures suggest that acid-sulfate alteration is present along the fault. Silicification and chloritization are found but are minor.

3.4.10 Fraser mines

The Fraser mines, also known as the Fraser-Martin and Fraser Brothers mines, lie along the Twin Peaks fault in sec. 8, 9, 16, 17, 18, T16S, R21W. Development consists of four shafts, 4-9 m deep, and several trenches, and seven adits, 2-18 m long (Fig. 3.18). Production is unknown, but Briggs (1982) reports a total production for mines in the northern part of the district (Twin Peaks, Commerce-Mayflower, etc.) as 1,000 tons yielding 1,115 oz Au, 3,640 oz Ag, and 1,965 lbs Cu (see discussion on Twin Peaks mine, this report). The mine was worked in 1958.

The deposit consists of quartz veins and silicified breccia along the Twin Peaks fault. The fault has a strike of N40°-50°W but the dip could not be measured. The fault throws andesite of Dark Thunder Canyon formation and younger ash-flow tuff against andesite of Summit Mountain. The fault zone consists of quartz, calcite, iron oxides, malachite, and manganese oxides. Silicification, hematization, and clay alteration are common. Briggs (1982) reports assays that range from 0-0.01 oz/ton (0.3 ppm) Au, 0-1.0 oz/ton (34 ppm) Ag, and as much as 0.7% Cu, 0.02% Pb, and 0.02% Zn (Fig. 3.18).

3.5 Description of copper-silver mines

3.5.1 Blue Bell mine

The Blue Bell mine, also known as the Shamrock or Blue Bird mine, is located in Cottonwood Canyon along the northwest-trending Blue Bell fault in sec. 8, T17S, R20W. The claims are unpatented and the main shaft is at an approximate elevation of 1646 m.

The principle development work has been at the Blue Bell shaft which is approximately 61 m deep (Fig. 3.19). Two levels occur at 15 m and 30 m depths. A 41-m long adit intersects the 30-m level, and a second adit, about 40 m long, intersects the 15-m level. The underground workings are caved and inaccessible in 1993. A water well, supplying the nearby Croom ranch, intersects the shaft at a depth of 37 m (Gillerman, 1964). Numerous trenches and pits expose the vein along strike. In 1990, Nova Gold Resources Ltd. drilled

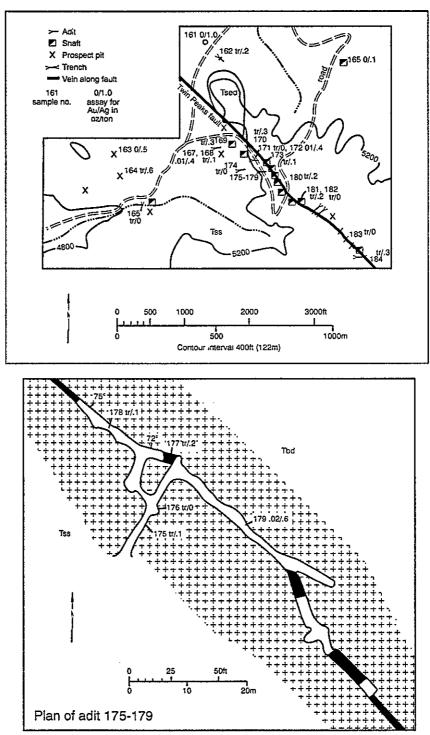

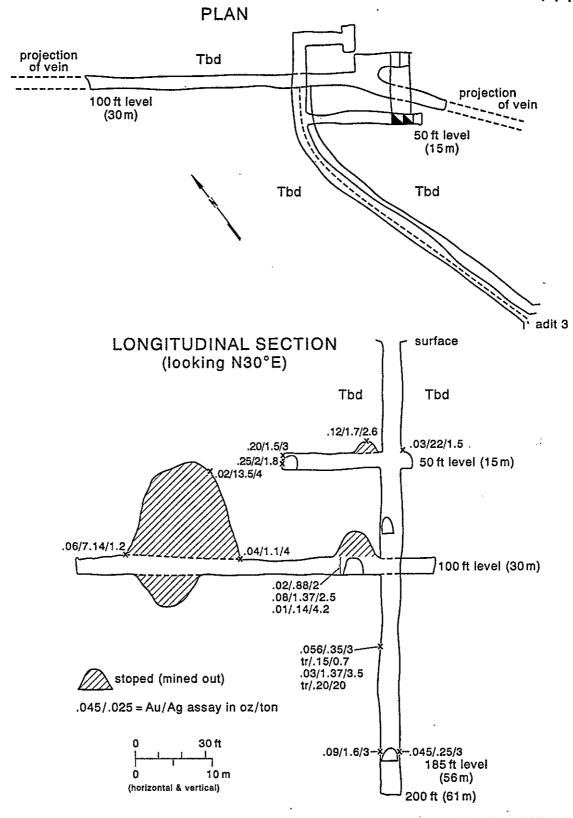

Fig. 3.18 - Map of Fraser Mines area (modified from Briggs, 1982; geology modified from V.T. McLemore mapping and Hedlund, 1993).Tss-Summit Mountains formation, Tbd-Dark Thunder Canyon formation, Tsed-undifferentiated sedimentary rocks (maps 1,2).

3,

Figure 3.19 Longitudinal section and plan of the Blue Bell mine (modified from H. Schmidt, unpubl. report, January 28, 1938). Tbd—andesite of Dark Thunder Canyon formation

several diamond drill holes northwest of the shaft along the Blue Bell fault, but no economic intercepts were reported.

Early mine reports indicate a high-grade pocket of ore was found and mined prior to 1904. Production from this ore pocket is reported as 254 tons of ore averaging 0.96 oz/ton (33 ppm) Au, 4.5 oz/ton (394 ppm) Ag, and 11% Cu (C. W. Davis, unpubl. report, 6/14/37). The mine also yielded a few hundred tons of ore in 1909, 1916, and 1918. One smelter lot of 33.4 tons of ore assayed 0.87 oz/ton (30 ppm) Au, 11.8 oz/ton (404 ppm) Ag, and 4.9% Cu (C. E. Morgan, unpubl. report, 10/14/21). However, total production is probably less than 500 tons of ore averaging between 0.6-0.9 oz/ton (20-31 ppm) Au, 10-12 oz/ton (340-411 ppm) Ag, and 6-11% Cu (NMBMMR files).

Two veins occur at the Blue Bell mine, although typically only one vein is exposed at the surface. The No. 1 vein averages 1 m wide and rarely exceeds 1.5 m in width. The No. 2 vein is up to 15 m wide. The veins dip nearly vertical to about 80°E to 80°W and strike N45-60°W. On the 30 m-level, the vein is reported to be 3 m wide (G. A. Kalor, unpubl. report, 4/6/14). Host rocks are silicified porphyritic andesite to basaltic andesite of the Dark Thunder Canyon formation. Ore minerals include malachite, azurite, chrysocolla, chalcopyrite, bornite, and chalcocite in a gangue of quartz, calcite, pyrite, hematite, and minor feldspar, chlorite, and titanium oxides (Appendix 11.3). The center of the veins is commonly formed by bladed calcite, locally replaced by quartz (lattice texture). It is reported that copper carbonate minerals are found only above the 15-m level (C. E. Morgan, unpubl. report, 10/14/21). The copper-silver vein grades to gold-silver at depth.

- ----

Early mine reports also describe fine-grained streaks of bornite, about 1.2 m wide, that assayed 0.03 oz/ton (1 ppm) Au, 27.3 oz/ton (936 ppm) Ag, and 27.8% Cu (W. H. Seaman, unpubl. report, 5/21/22). Underground sampling by H. Schmidt (283 samples) averaged 0.34 oz/ton (12 ppm) Au and 4.65 oz/ton (159 ppm) Ag; average assays decreased with increase in depth (Map B; H. Schmidt, unpubl. report, 2/1/38).

Surface sampling for this report detected no significant gold or silver values except for

one sample that assayed 1 oz/ton (34 ppm) Ag (#31, Appendix 11.6). Copper values ranged from 8 to 26,700 ppm; lead and zinc values are low (#31, 32, 296, Appendix 11.6).

3.5.2 Delmir Mine

Very little is known about the Delmir mine. Various spellings of the name occur in the literature: Delmire, Delamar, Delmar, and Delmare, and it is also known as the Copper Hill mine. The mine occurs on the Delmir fault, which trends north-northeast, N20°E and dips 70° west (Fig. 2.18). The mine is located west of Alabama Ridge in sec. 36, T17S, R21W. Development consists of several shallow shafts and pits and trenches (at least 6 m deep). The mine was worked in the early 1900s but production in 1915 and 1917 amounts to less than 200 tons of ore which averaged 0.02 oz/ton (0.7 ppm) Au, 2.66 oz/ton (91 ppm) Ag, 0.07% Cu, and 0.15% Pb.

The ore at the Delmir occurs in andesite of Dark Thunder Canyon formation and Bloodgood Canyon Tuff. Copper carbonates (malachite, azurite) and chrysocolla occur with calcite, feldspar, and minor quartz and clay or disseminations within the andesite and tuff, thin veinlets, and fracture coatings. The andesite and tuff are not extensively altered and silicification is minor. Two samples were collected and assayed and contained 0-0.03 oz/ton (1 ppm) Au, 1.42-2.29 oz/ton (49-79 ppm) Ag, 0.81-0.58% Cu, 60-239 ppm Pb, and 240-1190 ppm Zn (#263,372; Appendix 11.2, 11.6).

3.5.3 Hext mine

The Hext mine lies along the Apache fault near the projected intersection of the Blue Goose fault in sec. 20, T17S, R20W. Development consists of trenches, pits, caved shafts, and a caved adit. Very little is known about the history of this mine, and production is unknown.

The fault strikes N60°W but the dip is unknown. The deposit consists of a silicified breccia zone with quartz, malachite, azurite, chryscolla, and traces of calcite. The andesite is

silicified and locally altered to clay. Three samples were collected and assayed for this report and contained 0.014-0.017 oz/ton (0.5-0.6 ppm) Au, 0.6-5.2 oz/ton (20-178 ppm) Ag, 0.2-3.7% Cu, 72-280 ppm Pb, and 25-57 ppm Zn (#639, 640, 641; Appendix 11.6).

3.5.4 Wampoo mine

The Wampoo mine lies on the Commerce-Mayflower fault, southeast of the Commerce-Mayflower mine, in sec. 15, T6S, R32E. Development consists of three inclined shafts (probably less than 20 m deep), short adit, trenches, pits and drill holes. Production is runknown but probably includes part of the production reported by Keith et al. (1983; see

The deposit consists of silicified and brecciated andesite cut and cemented by quartz, calcite, azurite, malachite, fluorite, feldspar, illite/smectite, iron oxides (including goethite), chrysocolla, pyrite, and possibly chalcopyrite (#1068a, b; Appendix 11.3). Veins of white, massive calcite 5-8 cm wide cut across the breccia and quartz veins. The Commerce-Mayflower fault strikes N35°W at the Wampoo and dips 68° west. Some calcite veins strike N45°W and dip 52° west. Splays and branches along the fault are common. Two samples collected for this study contained no gold, 0-0.36 oz/ton (12 ppm) Ag, 0.11-0.31% Cu, 0.66-1.6% Pb, 0.72-1.1% Zn, and 0.08-0.04% CaF₂ (#1068a, b; Appendix 11.6).

3.5.5 Commerce-Mayflower mines

The Commerce-Mayflower group of mines lie on the Commerce-Mayflower fault in sec. 9, 10. 15, 16, T6S, R32E in Greenlee County, Arizona. Development consists of four shafts, 3-30 m deep, prospect pits, and trenches (Fig 3.20; Briggs, 1982). Production is unknown but probably includes part of the production reported by Keith et al. (1983; see discussion of Twin Peaks mines, this report).

The deposit consists of malachite, azurite, chrysocolla, pyrite, quartz, calcite, iron oxides, clay, and fluorite along the fault and fracture surfaces and as veins. Briggs (1982)

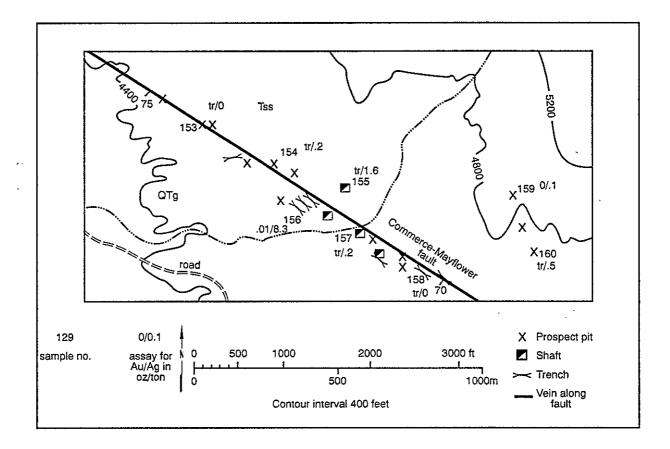

Fig. 3.20 - Map of Commerce-Mayflower Mine area (modified from Briggs, 1982; assays from Briggs, 1982; geology modified from V.T. McLemore mapping and Hedlund, 1993). Tss- Summit Mountain formation, QTg-Gila Group

. .

reports the presence of native copper, chalcopyrite, covellite, and chalcocite. The andesite is silicified and contains chlorite. Clay alteration occurs along parts of the fault for 2-3 m. The fault has a strike of N55-60°W and dips 75° west. Assays reported by Briggs (1982) range from 0-0.01 oz/ton (0.3 ppm) Au, 0-8.3 oz/ton (34 ppm) Ag, 0.17-15.4% Cu and as much as 0.01% Pb and 0.01% Zn (Fig. 3.20).

3.5.6 Copper Basin

The Copper Basin prospects, also known as the Lotty-Independence prospect, lies west of Twin Peaks in sec. 10, T6S, R32E in Greenlee County, Arizona. Development in the vicinity consists of prospect pits, six adits (4-30 m long), seven shafts (3-9 m deep), and several trenches (Fig. 3.21; Briggs, 1982). Production is unknown but probably includes part of production reported by Keith et al. (1983; see discussion of Twin Peaks mines, this report).

The deposit consists of malachite, azurite, quartz, pyrite, and calcite in veins and along fracture coatings. The andesite is silicified and contains epidote and chlorite. The rhyolite is also silicified. The faults strike N35°W with a near vertical dip. Briggs (1982) reports assays of samples collected that contain 0.1-1.3 oz/ton (3-44 ppm) Ag, 0-0.03 oz/ton (1 ppm) Au, and <0.01-3.2% Cu (Fig. 3.21). A sample collected and assayed for this study contained no gold, 1.25 oz/t (43 ppm) Ag, 6.7% Cu, <20 ppm Pb, and 24 ppm Zn (#1085, Appendix 11.6).

3.6 Description of fluorite mines

3.6.1 Mohawk mine

The Mohawk mine occurs south of Bitter Creek at the northwestern end of the Bilalli-Norman King fault near the intersection with the Bitter Creek shear zone (Map 1, 2). It lies northwest of the Norman King mine in sec. 26, T16S, R21W. Formerly it was called the Bitter Creek mine and on some maps it is mislabeled as the Bilalli mine. Biron Bay Resources

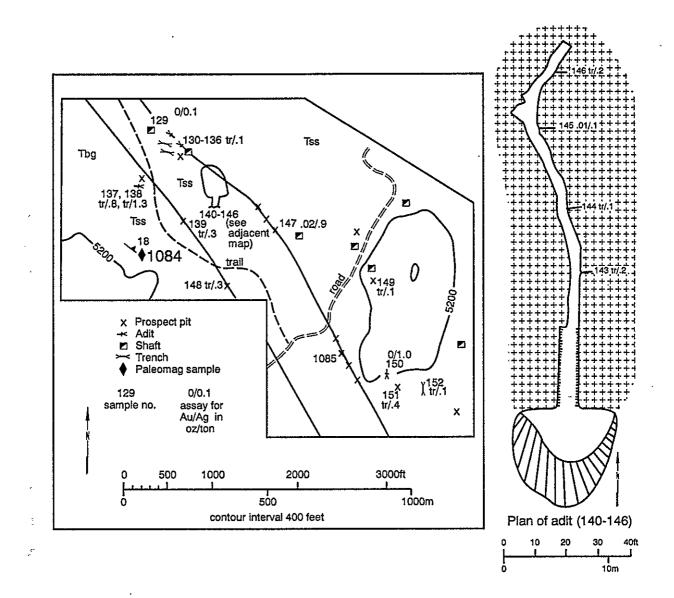

Fig. 3.21- Map of mines in Copper Basin mines area, west of Twin Peaks. (modified from Briggs, 1982; assays from Briggs, 1982; geology from V. T. McLemore mapping and Hedlund, 1993) #1085 collected for this study (appendix 11.6). Tss-Summit Mountain formation, Tbg-Bloodgood Canyon Tuff

Ltd. currently holds the lease.

21.

Development consists of four shafts (15, 15, 24, and 61 m deep), drifts, trenches, and prospect pits (Gillerman, 1964; McAnulty, 1978). One shaft, 24 m deep, connects to a drift which is 91 m long (Rothrock et al., 1946). Most of the workings are caved, flooded, and inaccessible.

The mine first yielded production in the 1940s when Southwestern Minerals Co. operated it (Williams, 1966). Total production from 1940 to 1941 was 6,463 tons of ore averaging 60-70% CaF₂ and 30-35% SiO₂ (McAnulty, 1978). One ore shoot was 1.8 m wide, 30 m long, and was mined to a depth of 24 m. In 1972, Jim McBee operated the mine and shipped 40-50 tons of ore to Deming, New Mexico (McAnulty, 1978). Total production is estimated to be about 6,500 tons of ore averaging 50-70% CaF₂.

The Mohawk deposit is fault controlled. The main vein strikes N10-15°W and dips 80°E to vertical. Ore minerals consist of green to purple to colorless fluorite in a gangue of quartz, pyrite, hematite, calcite, barite, and manganese oxides. The fluorite is massive to fine-grained. Bladed quartz after calcite is common and fluorite typically occurs within the blades. Fluorite grades to the south into quartz veins with local pods of fluorite. Fluorite is found along the Bilalli-Norman King fault as far southeastward as the Hoover Tunnel. The andesites hosting the veins are silicified. No gold, silver, copper, lead, or zinc values were detected in a sample collected for this report (A#1012, Appendix 11.6). Fluorite reserves are probably minimal.

3.6.2 Black Willow prospects

The Black Willow prospects lie north of Bitter Creek along the Twin Peaks fault in sec. 22, T16S, R21 W (Map 2). This group of prospects consists of several pits, four shafts (up to 24 m deep) and about 61 m of drifts (N. Walcott, unpubl. report, 12/15/39). The prospects were developed in the 1920s (Gillerman, 1964; Biggerstaff, 1974), but there is no reported production.

The vein consists of brecciated and silicified andesite cut by veins of clear to white to green fluorite, quartz, calcite, pyrite, illite, feldspar, iron oxides, pyrolusite and other manganese oxides, and traces of barite. Manganese oxides typically coat the fluorite. Locally, yellow staining of mottramite can be found. Gillerman (1964) reports gold and silver with pyrite were found. Fluorite grades to quartz veins to the northwest. The vein strikes N45°W with a variable dip of 70° to the northeast to vertical and is 7-15 m wide. Changes in dip and strike along the fault appear to concentrate mineralization (McAnulty, 1978; Biggerstaff, 1974). The fault brings Dark Thunder Canyon formation in contact with Summit Mountain formation. Fluorite is found sporadically along the entire length of the vein (at least 900 m), but decreases in concentration to the northwest. Fluorite occurs as massive pods and veinlets within quartz veins and as disseminations and veinlets along the face of fractures and faults. Locally, quartz after bladed calcite and bladed calcite occur. Five samples were assayed and found to contain no gold, 0-0.42 oz/ton (ppm) Ag, 14-290 ppm Cu, 16-250 ppm Pb, and 17-370 ppm Zn (#1011, 1106, 1130, 1131, 1131g, 1131f; Appendix 11.3, 11.6). Sample #1131f contained 32.4% CaF₂. Samples collected by Biggerstaff (1974) reportedly averaged 16.7% CaF₂ and 83% SiO₂. Alteration is minor in the Dark Thundér Canyon formation and consists of silicification and minor clay alteration. Acid-sulfate alteration occurs in the Summit Mountain formation; the relationship of this alteration to mineralization will be discussed separately.

3.6.3 Powell mine

The Powell mine, also known as the Fork mine, lies south of Bitter Creek in sec. 18, T16S, R21W (Map 2). Development consists of a bulldozer trench and several prospect pits. Production from March 1942, to January 1943 amounts to 127 tons of ore averaging 0.59% CaF₂ and 41% SiO₂ (Rothrock et al., 1946; Williams, 1966; Biggerstaff, 1974; McAnulty, 1978). Eugene Belcher conducted a percussion drilling program in 1973 and drilled four holes to 27 m. Belcher reported one ore intercept of 2 m at 27 m depth (Biggerstaff, 1974).

The Powell mine occurs along a northwest-trending fault that is cut by two east-westtrending faults of the Bitter Creek shear zone (Map 1, 2). Typically, fluorite occurs as thin veins, stringers, and fracture coatings along porphyritic andesite of the Summit Mountain formation in zones as wide as 15 m. At the mine, fluorite occurs as veins up to 1 m wide in a 10-m-wide zone. The vein at the surface is less than 200 m long. The main vein along the fault strikes N80-85°W and dips steeply to the west. Ore consists of coarse- and fine-grained, green to blue to purple to colorless fluorite in a gangue of quartz, calcite, iron oxides, 'manganese oxides, clays and barite. One sample from a pit above the mine assayed no gold or silver, 223 ppm Cu, 162 ppm Pb, and <100 ppm Zn and consisted of quartz, fluorite, 'calcite, jarosite, pyrite, and goethite (A#984, Appendices 11.3, 11.6).

3.6.4 Leta Lynn mine

4. Ť.

The Leta Lynn mine is located north of Bitter Creek, northwest of the Powell mine in sec. 7, T16S, R21W (Map 2). Development consists of several bulldozer trenches and prospect pits. Eugene Belcher discovered the deposit in 1971 and in 1972 produced 3 tons of fluorspar ore. Belcher also drilled three percussion drill holes in 1972 which showed that the width of the zone varies but averages 2 m in these holes (Biggerstaff, 1978).

The Leta Lynn mine occurs along a northwest-trending fault, probably the same fault system as the Powell mine. The Leta Lynn fault is offset to the south by an east-west-trending fault that is part of the Bitter Creek shear zone. To the northwest, the Leta Lynn fault is overlain by alluvium, but most likely continues into section 25, T6S, R32E where prospects have exposed portions of the fault (Maps 1, 2). Fluorite occurs as thin veins, stringers, and fracture coatings along porphyritic andesite of the Summit Mountain formation. The main vein strikes N80-85°W and dips 80-85°W and is up to 6 m wide and 300 m long. Ore consists of coarse- and fine-grained fluorite (green to blue to colorless) in a gangue of quartz, calcite, barite, clay, pyrite, iron, and manganese oxides. Some calcite is bladed; locally quartz replaces bladed calcite. Fluorite is intergrown with bladed quartz and calcite and also occurs between the bladed quartz.

3.6.5 Fourth of July mine

The Fourth of July mine is in the Daniels Camp area in sec. 33, T6S, R32E and sec. 4, T7S, R32E in Greenlee County, Arizona. Development consists of several trenches and an inclined shaft 45 m deep with drifts at depths of 17, 31, and 45 m (Fig. 3.22; Trace, 1947; Meeves, 1966; Richter and Lawrence, 1983). Production in 1936-1942 and 1960 by Southwestern Minerals Co. and D. R. T. Ellis Mining Co. amounted to about 3,190 tons of 64% CaF₂ (Richter and Lawrence, 1983).

The Fourth of July and adjacent deposits consist of brecciated and silicified veins. Fluorite occurs as breccia cement, veins, disseminations, and pods within faults and fractures. The Fourth of July fault trends N35-45°W with a 60° dip to the southwest. A cross fault with a strike of N65°W and a 60° dip to the south cuts or merges with the northwest-trending Fourth of July fault, and the mine occurs near the junction of the two faults. North-trending faults in the immediate area host quartz veins with some fluorite locally.

The deposits consist of green to colorless fluorite, quartz, calcite, feldspar, kaolinite, rutile and other titanium oxides, and manganosite and other manganese oxides (Appendix 11.3). The silicified breccia at the Ellis shaft, east of the Fourth of July mine (Map 2), consists of quartz, fluorite, malachite, azurite, chrysocolla, calcite, and manganese oxides. Clay is common along the footwall. Silicification of the andesite of Dark Thunder Canyon is minor. Several stages of quartz deposition occurred: some quartz is overgrown with fluorite and calcite, whereas other quartz replaces or overgrows calcite. Fluorite occurs on quartz, as cubes within vugs, and crosscutting veinlets and is coated by manganese oxides.

Chemical analyses of these fluorite veins are variable. Trace (1947) reports assays containing up to 1-2% WO₃ locally with manganese oxides. Meeves (1966) reports analyses, using a radioactive beryllium detector, containing as much as 100 ppm Be in some veins, but spectrographic analyses by Hedlund (1990a) failed to detect any beryllium. The beryllium is

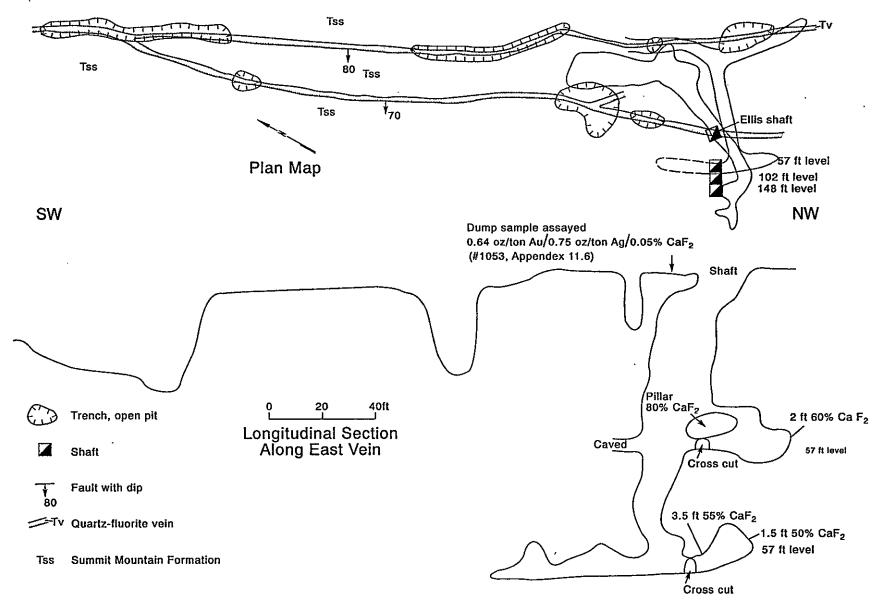

Figure 3.22- Plan and section along Fourth of July fluorspar mine (modified from Trace, 1944).

155

.

attributed to be bertrandite or helvite (Powers, 1976), but this identification is speculative and needs to be confirmed. Neither tungsten nor beryllium were analyzed for in this study. Two samples of veins in the Fourth of July mine area collected and assayed for this study contained 0-0.64 oz/ton (0-22 ppm) Au, 0-0.75 oz/ton (0-26 ppm) Ag, 46-16,000 ppm Cu, 27-62 ppm Pb, 30-50 ppm Zn, and 0.05-0.3% CaF₂ (#1042, 1053; Appendix 11.6).

3.6.6 Daniels Camp mines

The Daniels Camp mine lies just west of the mapped area in sec. 5, T7S, R32E in Greenlee County, Arizona. Development consists of several trenches, pits, and a shallow shaft (probably less than 10 m). The property was worked during the 1940s (Biggerstaff, 1974), but production, if any, is unknown.

Fluorite occurs as veins, pods, disseminations, thin veinlets, and fracture coatings along faults and fractures trending N10-15°E and N5°W and dipping near vertical (Biggerstaff, 1974; Richter and Lawrence, 1983). The mineralized zone rarely exceeds 2 m width at the surface. The veins consist of green to colorless fluorite, calcite, quartz, local pyrite, manganese oxides, iron oxides, clay, and traces of barite. Alteration of andesites of the Summit Mountain formation is mild to weak and consists of a zone 1-2 m wide of silicified or clay altered rock. Brecciation is common. Biggerstaff (1974) estimates the fluorite content as approximately 30-35% CaF₂.

3.6.7 Forbis mine

The Forbis mine, also known as the Polly Ann, occurs in sec. 4, 9, T7S, R32E in Greenlee County, Arizona. Development consists of three shafts, up to 57 m deep, with drifts and trenches. Some fluorite was produced, probably in the 1940s and again in 1982, but total production is unknown. The shaft has two compartments and is filled with water.

The Forbis deposit occurs along a minor, poorly exposed fault trending N15°-45°W and dipping 65° southwest. At the surface the deposit is about 2 m wide and less than 300 m

long. Fluorite is green to yellow to colorless and occurs as pods, veins, irregular masses, disseminations and thin veinlets with andesite and along fracture surfaces. A sample collected and assayed for this study contained no gold or silver, 86 ppm Cu, 52 ppm Pb, 20 ppm Zn, and 7.47% CaF₂ (#1041, Appendix 11.6). Minor silicification of the andesite (Summit Mountain formation) occurred along the fault. Some clay alteration also has occurred along the footwall.

3.6.8 Luckie mines

The Luckie No. 1 and Luckie No. 2 shafts are in sec. 3, 10, T7S, R32 E in Greenlee County, Arizona. Development consists of two inclined shafts (both 27 m deep), pits, and trenches (Figs. 3.23, 3.24; Trace, 1947). More than 2,200 tons of 65-70% CaF₂ were produced intermittently from 1914 to 1944 by Quien Sabe Mining Co. (Richter and Lawrence, 1983; Hedlund, 1990a).

Deposits at the Luckie mines consist of fluorite (green to blue to colorless), quartz, calcite, and manganese oxides with trace pyrite, chalcopyrite, and chrysocolla. The fluorite occurs as breccia cement, pods and irregular masses, and veins within the quartz along the margins of a rhyolite dike. Quartz is intergrown with fluorite and manganese coats both quartz and fluorite. The veins vary in width from 3-6 m and are less than 100 m long, although fluorite occurs along the Luckie No. 1 fault sporadically for 300 m or so. The veins occur in acid-sulfate altered andesites of Summit Mountain formation. The Luckie deposits occur along separate faults. The Luckie No. 1 fault has a strike of N15°E with a west dip of 75°. The Luckie No. 2 fault has a strike of N35°W with a near vertical dip. A sample collected for this study contained no gold or silver, 43 ppm Cu, 80 ppm Pb, and 60 ppm Zn (#559, Appendix 11.6). Hedlund (1990a) reports an analysis of a sample from the Luckie No. 2 mine that contained 0.03 oz/ton (1 ppm) Ag, 150 ppm Ba, 15 ppm Cu, 20 ppm Zn, and 15 ppm Pb. Meeves (1966) reports an assay, using a radioactive beryllium detector, containing as much as 100 ppm Be from the Luckie mines. The beryllium is attributed to bertrandite or

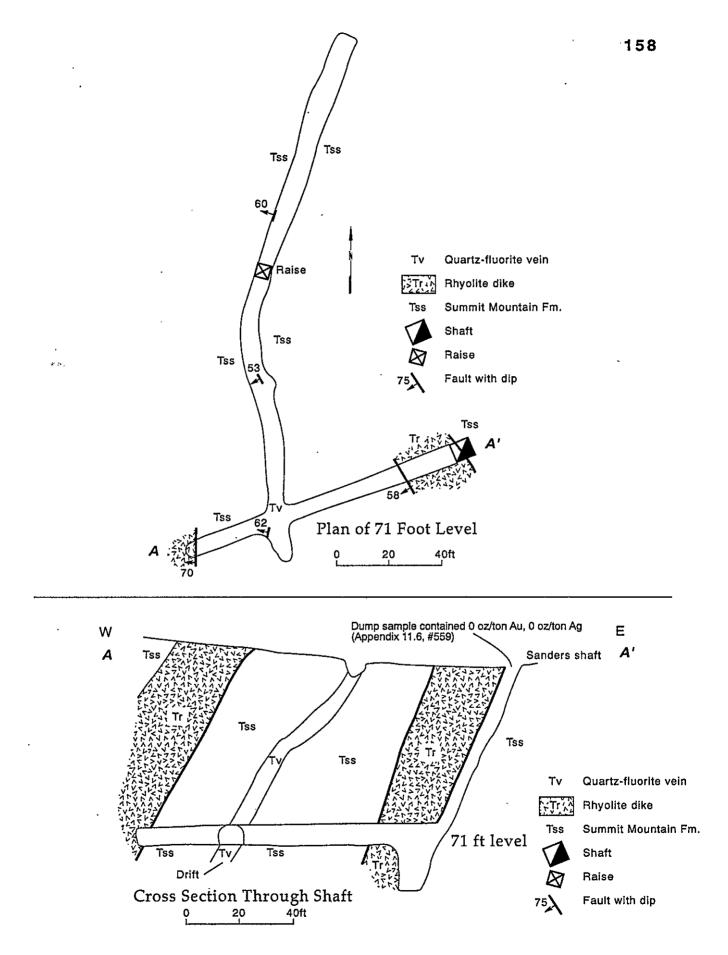

Figure 3.23- Plan and section of Luckie No. 1 fluorspar mine (modified from Trace, 1944).

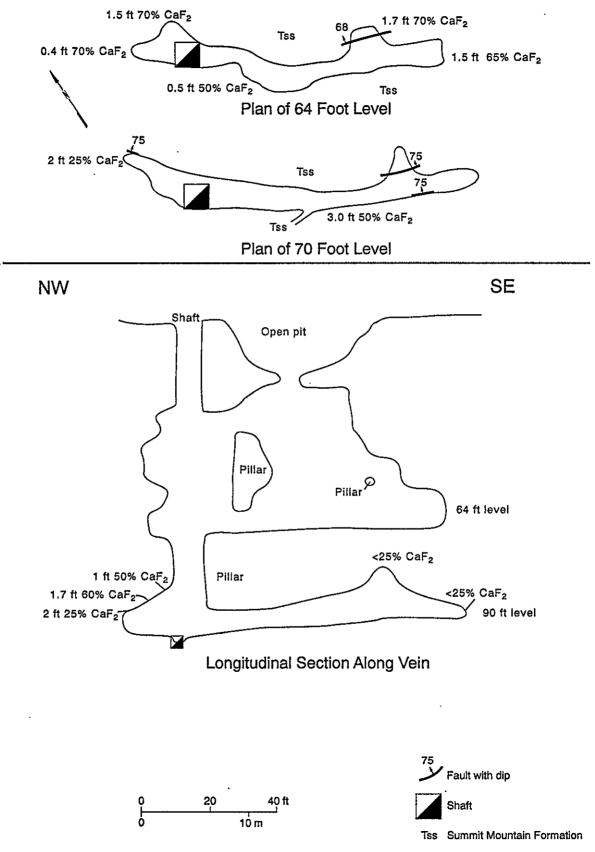

Figure 3.24- Plan and section of Luckie No. 2 fluorspar mine (modified from Trace, 1944)

helvite (Powers, 1976), but the identification is speculative and needs to be confirmed.

3.6.9 Goat Camp Springs mines

Several fluorite mines occur in the Goat Camp Springs area west of Vanderbilt Peak (Dean, Stotts, Ontario, Rattlesnake No. 1, Rattlesnake No. 2) (Maps 1, 2). These occur along faults of varying strikes, typically N10°W to N10°E, but some veins occur along northwest-trending faults as well. Development consists of shafts, trenches and pits. Total production is unknown but presumed minor. Between 120 and 150 tons of fluorite was produced from the Rattlesnake mines in the 1970s by R. Hill (Hedlund, 1990b).

The veins occur along faults and fractures in altered andesite of Summit Mountain formation. Fluorite and quartz with varying amounts of iron oxides, clay, calcite, and barite occur within the veins. Some veins occur along rhyolite dikes, whereas other veins change from quartz and fluorite to quartz and pyrite along strike. Assays are variable but typically low (Appendix 11.6, Map 2).

3.7 Description of manganese mine

Manganese oxides are common throughout the Steeple Rock district, but only one mine was developed specifically for manganese, the Black Cat mine. The Black Cat mine lies in sec. 33, T6S, R32E north of the Goat Camp Springs area in Arizona. The claims were first located in 1952 by L. A. Billingsley and Lewis Dean. In 1953-55, 86 tons of ore averaging 43.2% Mn (74,500 lbs Mn) were shipped to Deming, New Mexico (Farnham et al., 1961). Development consists of prospect pits, trenches, and two shafts, 15 and 13 m deep. Psilomelane and other manganese oxides occur in two narrow veins up to 1 m wide and along fractures and joints several meters into the country rock adjacent to the veins. Calcite, fluorite, quartz, and iron oxides are also present. One sample collected for this study did not contain any gold or silver, but assayed 21.8% Mn (Black Cat, Appendix 11.6).

4. MINERALIZATION

4.1 Mineralogy

In this section, the distribution, textures, and description of the major minerals of the vein deposits are presented. Techniques used include literature search, field observations, petrography, XRD, SEM, and chemical analyses (see section 1.5.3 for specific methods used).

4.1.1 Ore mineralogy

4.1.1.1 Gold, Au—Gold and silver are the most economically important minerals in the Steeple Rock district. Native gold is reported from numerous base-metal and gold-silver veins from throughout the district (Lindgren et al., 1910; Griggs and Wagner, 1966; Gillerman, 1964; unpublished reports). Most of the gold may actually be electrum, the natural occurring alloy of gold and silver which, by definition, contains more than 20% Ag.

Gold occurs as submicroscopic to rare visible flakes disseminated in complex quartz breccias. Typically gold is difficult to detect except by fire assay. Some wire gold is reported to occur at the Carlisle, Center, and other mines (D. Hanson, pers. comm. 1991). Native gold or electrum was found disseminated with fine-grained sulfides and disseminated in "blue" quartz in drill hole J87-3 at the Jim Crow-Imperial mines (Appendix 11.3; Queenstake Resources Ltd., unpubl. report, April 1982). It is associated with high gold assays (up to 2.2 oz/ton Au), however that section of the drill core is missing and no longer available for study. A sample from the Alabama vein contained a small flake of gold or electrum in a vug within quartz-hematite breccia. At the Summit vein, gold occurs in two associations: (1) electrum (with as much as 37% Ag content) occurs with silver sulfides and (2) native gold (with low silver) occurs with pyrite or iron oxides and in quartz-carbonate veins (W. Baum, unpubl. report, March 31, 1988).

Mineral concentrates from the Center mine were also examined. Only three grains of electrum were found by SEM, despite hours of examination (Wilson et al., 1993). The grains

were small (<200 μ m), free grains and not intergrown with sulfides. EDS x-ray patterns indicate that these grains are electrum (Fig. 4.1). Figure 4.2 shows a back-scattered image (SEM) of an electrum grain adjacent to a grain of chalcopyrite. The x-ray scan maps show the concentration and distribution of copper, gold, and silver (Fig. 4.2). Note the purity of the grains. Metallurgical tests indicate that most of the gold and silver can be recovered from Pb-Cu flotation and only minor gold and silver occurs with the zinc and pyrite concentrates (Wilson et al., 1993; I. Gundiler and M. Brueggemann, unpubl. report, May 25, 1990).

In general, gold in the Steeple Rock district is rarely visible and the only sure detection is by fire assay. As previously stated, the gold most likely occurs as electrum or as native gold, and is associated with pyrite. It is found in complexly brecciated quartz veins. Gold and silver are strongly correlated in most deposits (Fig. 4.3), but not with other elements. Gold may be sporadically distributed within individual veins making grade control challenging.

4.1.1.2 Silver, Ag-Silver is typically more abundant than gold in the vein deposits of the Steeple Rock district (Appendix 11.6, Table 3.2), but identification of silver minerals is difficult because of their small size. Silver also occurs in electrum, in concentrations much less than gold; silver must occur in other minerals besides electrum because silver concentrations are typically greater than gold concentrations. Native silver is reported to occur at the Ontario mine (Griggs and Wagner, 1966). Numerous reports indicate that silver occurs as argentite, Ag_2S (Lindgren et al., 1910; Gillerman, 1964; unpublished reports), but argentite is not stable at room temperature and inverts to acanthite Ag_2S (Anthony et al., 1990). Therefore, most argentite is probably acanthite, although it was likely to have been deposited as argentite, if formed at greater than 176°C.

Cerargyrite (chlorargyrite), AgCl, is reported in the district (Gillerman, 1964), and occurs as an alteration product at the Carlisle mine (SEM study by W. Baum, unpubl. report, March 31, 1988), where it occurs as intergrowths with chalcopyrite, secondary copper minerals, and acanthite. Ultra-fine ($< 5 \mu m$) native silver was found with iron and manganese

••

165

oxides and as argentojarosite, Ag Fe₃ $(SO_4)_2$ $(OH)_6$, at the Summit vein (W. Baum, unpubl. report, 1988). W. Baum also reports silver occurring with tetrahedrite or other sulfosalts in the Carlisle and East Camp veins.

High silver values typically occur in complexly brecciated quartz veins, probably as fine disseminations or thin streaks of sulfides. Many samples coated or stained with mottramite or mimetite contain high values of gold and silver. Locally, silver concentrations correlate well with lead concentrations, suggesting that argentiferous galena may be present. In general, the only sure detection of silver is by fire assay.

4.1.1.3 Sphalerite, (Zn, Fe)S—Sphalerite is common as massive aggregates and intergrowths with galena, chalcopyrite, and pyrite (up to several centimeters long) only in the base-metal vein deposits along the Carlisle fault, specifically the Carlisle, Center, Pennsylvania, and Ontario mines. Up to 10% sphalerite can be found locally in these deposits. Sphalerite is also present as small, disseminated flakes or aggregates, typically microscopic. (less than 0.5 mm) in samples from underground workings or drill core from gold-silver veins, specifically the Section 2, Alabama, Jim Crow, Imperial, McDonald, Summit, Bank, and Mohawk deposits. Zinc, most likely as sphalerite, was produced from the Carlisle, Center, Pennsylvania, Ontario, East Camp, Mt. Royal, and Summit mines. XRD patterns confirm the presence of sphalerite in most of these deposits (Appendix 11.3). Some deposits along the Foothills fault may also contain sphalerite; however, the XRD patterns are inconclusive because of interferences from other more abundant minerals (Appendix 11.3). Furthermore, zinc in excess of several hundred ppm occurs in samples from throughout the district and probably occurs as sphalerite (Appendix 11.5, 11.6). Sphalerite rarely exceeds 1% in any deposit other than those along the Carlisle fault.

÷

In polished thin section, sphalerite occurs as massive aggregates intergrown with

galena, chalcopyrite, and/or pyrite or as small monomineralic aggregates. Sphalerite is commonly optically anisotropic, even though it has a cubic crystal structure. This anisotropy is a result of impurities (Deer et al., 1975). The crystals are anhedral and irregular and twinning and growth bands are rare, as are skeletal textures. In reflected light, sphalerite is gray, locally with a brown tint, and internal reflections are common. In transmitted light, sphalerite ranges in color from honey yellow to various shades of brown, including reddish brown. Brown colors in sphalerite are typically attributed to the presence of Fe; red to Sn, In, Ag, and Mo; and yellow to Ge, Ca, Cu, Hg, and Cd (Deer et al., 1975). An EDS x-ray spectrum (SEM) of yellow sphalerite from the Center mine indicates that Cd and Fe are present in small concentrations (Fig. 4.4; from I. Gundiler in Wilson et al., 1993).

Most sphalerite from all types of samples from the Steeple Rock district displays various intergrowth textures with chalcopyrite (Fig. 4.5, 4.6) and, to a lesser extent, galena and pyrite. These sphalerites contain randomly dispersed and/or crystallographically oriented rows of rods and blebs of chalcopyrite, and rarely galena, each typically less than 30 μ m long. Some chalcopyrite replaces fluid inclusions in the sphalerite. This texture is similar to the myrmekitic and symplectitic textures of igneous rocks (MacKenzie et al., 1991) and is commonly referred to as "chalcopyrite disease" (Craig and Vaughn, 1981). Chalcopyrite, galena, and pyrite locally occurs along the rims of sphalerite as well as suturing fractures. Chalcopyrite disease has been commonly attributed to exsolution of dissolved copper on cooling of the sphalerite (Ramdohr, 1969). However, subsequent experimental studies (Wiggins and Craig, 1980; Hutchison and Scott, 1981) have demonstrated that sphalerite can not contain sufficient dissolved copper to produce the abundance of these chalcopyrite rods and blebs unless the temperatures of formation exceed 500°C. In the Steeple Rock samples (formed at less than 500°C), up to 30% chalcopyrite rods and blebs are visually estimated to

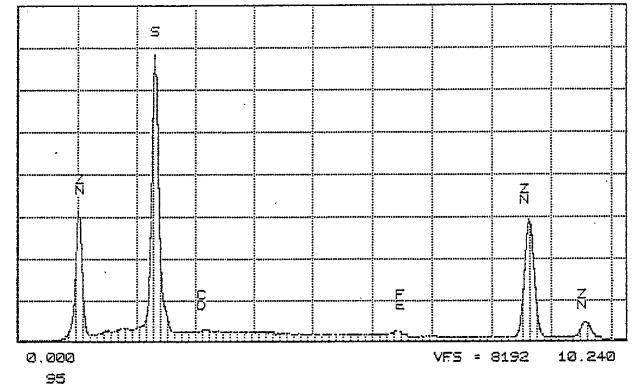

Figure 4.4—EDS x-ray spectrum of sphalerite from the Center mine (20 kv).

168

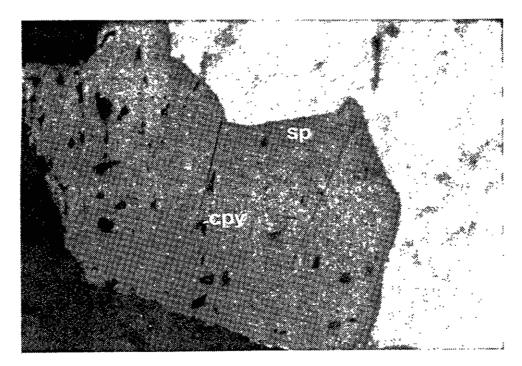

Figure 4.5—Photomicrograph of chalcopyrite disease in sphalerite, Carlisle mine. The chalcopyrite occurs as bright blebs within the sphalerite (sp). From drill hole H5 (depth of 52.1 m). Field of view is 0.325 mm.

Figure 4.6—Photomicrograph of chalcopyrite disease in sphalerite. From drill hole H13 (depth of 30 m). Field of view is 0.325 mm.

estimated to occur in some sphalerites. Chalcopyrite disease is common in epithermal vein deposits and additional studies suggest that this disease is a result either of replacement as copper-rich fluids react with sphalerite after formation or of epitaxial growth during formation with sphalerite (Craig and Vaughn, 1981; Eldridge et al., 1988; Barton and Bethke, 1987; Bortnikov et al., 1991). Pattrick et al. (1993) suggest that this texture is a result of preferential adsorption (irreversible) of copper in response to repetitive changes in fluid pH and temperature. Barton and Bethke (1987) have also suggested that the rods and blebs of galena may result from similar processes.

In other samples from Steeple Rock, sphalerite is intergrown with chalcopyrite, galena, and pyrite (Fig. 4.7), suggesting coprecipitation locally occurred (Bortnikov et al., 1991; Kojima, 1992).

4.1.1.4 Chalcopyrite, $CuFeS_2$ —Chalcopyrite is common as massive aggregates and intergrowths with galena, sphalerite, and pyrite only in the base-metal veins along the Carlisle fault. Up to 10% chalcopyrite is locally present. Chalcopyrite also is found in lesser amounts (typically less than 5%) in gold-silver and copper-silver veins. It occurs as small disseminations or aggregates, typically microscopic, in the silver-gold veins and as small disseminations commonly surrounded by secondary copper minerals in the copper-silver veins. The presence of chalcopyrite is confirmed by XRD (Appendix 11.3) and chemical assays (Appendix 11.5, 11.6).

Chalcopyrite is included in sphalerite (Figs. 4.5, 4.6) and rarely galena. It locally fills fractures in pyrite, galena, and sphalerite. An EDS x-ray spectrum of chalcopyrite from the Center mine shows no impurities (Fig. 4.8; Wilson et al., 1993). Locally, some zones of only chalcopyrite and pyrite occur in both base-metal and gold-silver veins. Elsewhere, chalcopyrite occurs with other sulfides. Copper was produced from many gold-silver and copper-silver deposits and probably occurred as chalcopyrite (Table 3.2). Some chalcopyrite is altered to or coated by secondary copper minerals and iron oxides.

4.1.1.5 Galena, PbS—Galena is common as massive aggregates and intergrowths

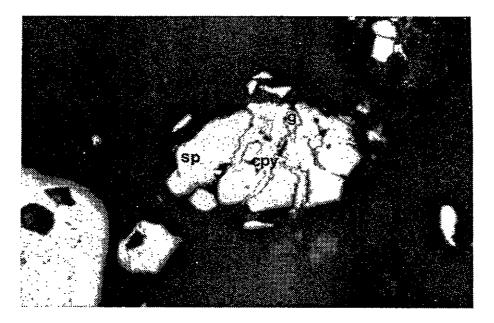

Figure 4.7—Photomicrograph of intergrown sphalerite (sp), chalcopyrite (cpy), and galena (ga), Center mine. Field of view is 0.325 mm.

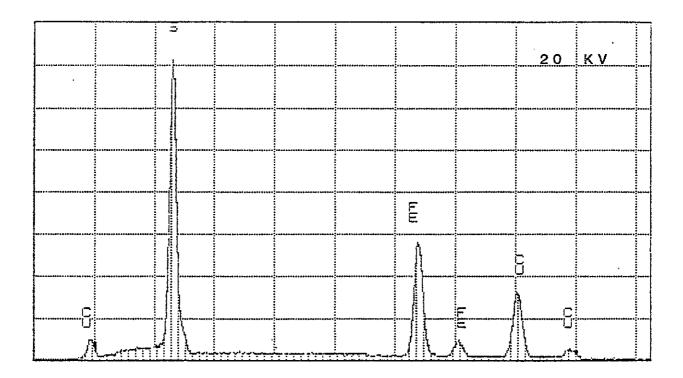

Figure 4.8—EDS x-ray spectrum of chalcopyrite from the Center mine.

with sphalerite, chalcopyrite, and pyrite only in the base-metal vein deposits along the Carlisle fault. It is rare in gold-silver veins where it occurs as fine-grained disseminations or thin black streaks in the quartz breccias. Galena also occurs in thin black streaks and as small disseminated aggregates in silicified and bleached andesite in drill hole M91-4 (Fig. 4.9). As much as 10% galena occurs in some ore shoots in base-metal veins, whereas galena rarely exceeds 1% in gold-silver veins. XRD patterns and chemical assays confirm the presence of galena in many deposits (Appendix 11.3, 11.5, 11.6). Despite the low concentrations, lead was produced as a byproduct from some gold-silver veins and probably occurred as galena (Table 3.2).

Galena is locally included in pyrite and sphalerite and locally fills fractures in pyrite (Fig. 4.10; Wilson et al., 1993). Some galena is cut by thin veinlets of chalcopyrite and sphalerite. Galena in gold-silver veins typically occurs as small monominerallic grains or intergrowths with sphalerite or pyrite.

An EDS x-ray spectrum of galena from the Center mine indicates that the galena contains few impurities of iron and silver (Fig. 4.11). However, assay data indicate a strong to moderate correlation locally between silver and lead, suggesting that argentiferous galena may be locally common.

4.1.1.6 Fluorite, CaF_2 —Fluorite occurs as an ore mineral in fluorite veins in several areas of the Steeple Rock district; specifically the Rattlesnake, Goat Camp Springs, Foothills fault (Daniels Camp), West Bitter Creek (Mohawk-Black Willow), and East Bitter Creek (Powell-Leta Lynn) areas (Map 2). Numerous fluorite veins and breccia zones are found throughout the entire depth of drill hole BCl (at least nine zones to a depth of 670.2 m, Appendix 11.1).

Fluorite occurs in veins, pods, breccia cement, and cubes and octahedrons in vugs and other open-spaces. Some zones are up to 2 m wide. Fluorite is typically colorless to white to yellow to green to blue and is locally stained black (manganese oxides) or red to brown (iron oxides). Fluorite also occurs in amygdules in the lava flows of Crookson Peak in the

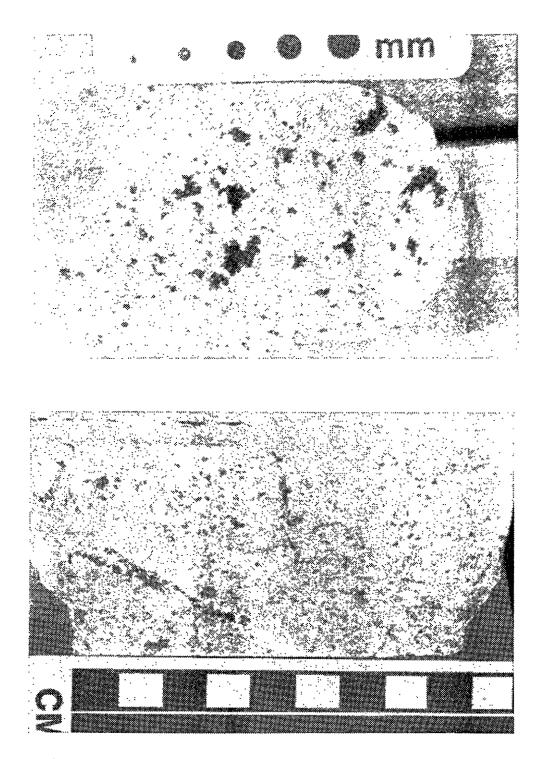

Figure 4.9—Galena disseminations and thin black veinlets within silicified and bleached andesite in drill core M91-4 (depth is 467 m), Summit vein. Drill core is 5 cm in diameter.

Figure 4.11-EDS x-ray spectrum of galena, Center mine.

northeastern portion of the area (Biggerstaff, 1974). It occurs as fine- to coarse-grained masses, disseminations in host rock and within bladed quartz and calcite. Brecciated, ribbon textures, and crustiform textures are common. Other minerals associated with these veins include pyrite, barite, calcite, and clay minerals.

Whereas Meeves (1966) reports the occurrence of as much as 100 ppm Be in some veins, and Trace (1947) reports the occurrence of as much as 1.97% WO₃ in some veins; these elements were not analyzed in this study. However, manganese and iron oxides are common and some veins contain minor amounts of mercury, up to 0.2 ppm (Appendix 11.5).

4.1.1.7 Other minor ore minerals and secondary minerals—This section contains a short description of other minor ore minerals and secondary ore minerals that occur in the Steeple Rock district. The minerals are arranged in alphabetical order and some minerals (designated by *) are suspect in their identification. Additional mineralogical work is needed because only field, petrographic and XRD studies were completed.

Anglesite, $PbSO_4$ —Anglesite occurs as rare secondary coating or alteration of galena in base-metal veins. It forms a white to gray coating on galena. It is a secondary mineral in the Steeple Rock district that occurs in the near-surface, oxidized portions of base-metal veins.

Azurite, $Cu_3(OH)_2$ ($CO_3)_2$ —Azurite occurs as secondary, blue coatings and poorly developed crystals on quartz and other minerals in base-metal, gold-silver, and copper-silver veins in the Steeple Rock district. It typically occurs with malachite, chalcopyrite, and other copper minerals (Appendix 11.3). It occurs in the oxidized, near-surface portions of the veins, although some drill-core samples from the Carlisle and Center mines do locally contain azurite coating chalcopyrite.

Bornite, Cu_5FeS_4 —Bornite is found in the base-metal and some copper-silver veins in the Steeple Rock district. It occurs as iridescent blue-purplish coatings on and alteration of chalcopyrite or chalcocite. It is a secondary mineral in the Steeple Rock district that occurs in the near-surface, oxidized portions of the base-metal and copper-silver veins.

Cerussite, PbCO₃—Cerussite is a common secondary, gray to black coating on galena

in the base-metal veins and some gold-silver veins (Appendix 11.3). It even occurs in some samples from the USBM drill core (#H10-279-279.8, Appendix 11.3). It occurs in the oxidized, typically near-surface portions of veins in the Steeple Rock district and indicates the presence of galena.

Chalcanthite, $C_{\mu}^{LSO_4} \cdot 5H_20$ —Crusts and fibers of blue to blue-green to green chalcanthite occur along the walls of many underground workings in the Steeple Rock district. The most abundant occurrence is in the Carlisle adit where chalcanthite forms crusts on the walls up to 10 centimeters thick. Crystals are fibrous and fragile. Chalcanthite is a recent, secondary mineral in the Steeple Rock district that indicates recent movement of acidic, copper-bearing waters. Water in the Carlisle mine has a pH of 2.5–3.5 (J. McLemore, unpubl. report, March, 1993).

Chalcocite, Cu_2S —Chalcocite occurs locally in base-metal and copper-silver veins in the Steeple Rock district (Griggs and Wagner, 1966; Gillerman, 1964). Thin bluish-black coatings of chalcocite occur on chalcopyrite in the Carlisle and Center mines. No crystals <u>or</u> aggregates have been found. Chalcocite in the Steeple Rock district is a secondary mineral that occurs in the oxidized portions of base-metal and copper-silver veins.

Chrysocolla, $(Cu,Al)_2H_2Si_2O_5(OH)_4 \cdot nH_2O$ —Chrysocolla is a rare mineral in coppersilver and base-metal veins in the Steeple Rock district. It is green to bluish-green, translucent to opaque, vitreous to dull luster, and occurs as coatings, incrustations, and rare botryoidal aggregates up to 1-2 cm across. Locally, it may have been mined for use as turquoise. It typically occurs on quartz, malachite, or other copper minerals, although it also occurs alone as thin, fracture coatings. It occurs in the near-surface portions of veins in the Steeple Rock district. Identification by XRD is confirmed in some samples (#708, 963, Appendix 11.3).

Covellite, CuS—Covellite occurs as an alteration or coating of chalcopyrite and chalcocite in the base-metal and some gold-silver veins. It is indigo-blue to black and iridescent. It is a secondary mineral in the Steeple Rock district that occurs in the oxidized, near-surface portions of the veins.

Cuprite, Cu_2O —Cuprite occurs as thin, secondary, red to red-brown coating on chalcopyrite in base-metal veins. It is bluish-white in reflected light in polished sections and is an alteration of chalcopyrite. Only one sample that was x-rayed (XRD) contained cuprite (#H9.367.6; Appendix 11.3). Cuprite is a rare, oxidized mineral in the Steeple Rock district.

Malachite, Cu₂(OH)₂(CO₃)—Malachite is common in many base-metal, copper-silver, fluorite, and gold-silver veins in the Steeple Rock district. It occurs as green coating and prismatic or fibrous crystals on quartz or fracture surfaces. Some coatings are up to 1-2 cm thick. Malachite is typically intergrown with and difficult to distinguish from pseudomalachite. Malachite in the Steeple Rock district locally is distinguished from pseudomalachite by a lighter green color and earthy appearance or no luster. Identification is confirmed by XRD (Appendix 11.3). Malachite occurs in all copper-silver veins. It also occurs as fracture coatings and amygdules in andesite in several areas of the district (Biggerstaff, 1974). Such occurrences found east of Twin Peaks led to core drilling of a 650m-deep hole. The core contained pyrite but low gold, silver, and copper values (Biggerstaff, 1974). Malachite in the Steeple Rock district occurs in the near-surface, oxidized portions of the veins and as fracture coatings locally along faults in andesite throughout the district.

Manganese oxides—Manganese oxides are common throughout the Steeple Rock district as fracture coatings and thin veinlets. They typically coat other vein minerals, although locally they are intergrown with white to black calcite. Various manganese minerals are present; manganosite MnO and pyrolusite MnO_2 are identified by XRD (Appendix 11.3). Most of the manganese oxides are probably psilomelane (romanechite) BaMnMn₈O₁₆(OH)₄. Manganese oxides are typically black, opaque, massive, and hard to soft, depending on amount of silicification. Manganese was mined at the Black Cat mine.

Mimetite, $Pb_5(AsO_4, PO_4)_3Cl$ —Mimetite is a common secondary yellow to brown coating on samples containing sulfides and detectable gold and silver assays. One sample from the Near Years Gift vein (#257a, Appendix 11.3) consisted of small (1-3 mm), yellow plates or tabular crystals on quartz breccia. Numerous samples contain mimetite detectable by XRD

177

(Appendix 11.3). It occurs in the oxidized, near-surface portions of the vein deposits in the Steeple Rock district and indicates a good possibility of detectable gold and silver values.

Mottramite, $(Cu,Zn)Pb(VO_4)(OH)$ —Mottramite is common as a secondary, yellowgreen coating on samples that contain detectable gold and silver concentrations. A sample from a vein south of Saddleback Mountain (#600, Appendix 11.3) contains mottramite on quartz breccia with illite, kaolinite, and pyrite. In the Steeple Rock district, mottramite occurs in the oxidized, near-surface portions of the veins.

Nantokite, CuCl—Nantokite occurs as a secondary coating or alteration of copper minerals in base-metal veins along the Carlisle fault. It typically occurs as thin white to whitish-blue coatings or granular aggregates on quartz and copper sulfides. It is identified primarily by XRD (Appendix 11.3). In the Steeple Rock district, it occurs as a secondary mineral in the oxidized, near-surface portions of base-metal veins.

Pseudomalachite, $Cu_5(PO_4)_2(OH)_4 \cdot H_2O$ —Pseudomalachite is common in all types of vein deposits except the manganese veins in the Steeple Rock district. It occurs as green \sim coatings or needle or radiating fibrous crystals and is typically associated with malachite. It occurs as fracture coatings, intergrown with malachite, and crystals and coatings on quartz and calcite. In the Steeple Rock district, identification of pseudomalachite is by XRD (Appendix 11.3), although locally it forms darker, brighter green, and more vitreous crystals than malachite. In the Steeple Rock district, pseudomalachite occurs in the oxidized, near-surface portions of the veins.

*Tennantite, $(Cu, Ag, Zn, Fe)_{12}(As, Sb)_4S_{13}$ —Tennantite may occur in two samples according to XRD patterns (#755, B91-17-534-535; Appendix 11.3). Typically tennantite is a less common mineral, but locally is abundant in hydrothermal vein deposits (Anthony et al., 1990). The XRD patterns are not conclusive, but it is possible that tennantite may occur in gold-silver veins in the Steeple Rock district.

*Tetrahedrite, $(Cu, Fe)_{12}Sb_4S_{13}$ —Tetrahedrite is reported in veins in the Steeple Rock district by Gillerman (1964) and W. Baum (unpubl. report, March 31, 1988). Its occurrence

178

in the district could not be confirmed in this study.

*Wulfenite, $PbMoO_4$ —While wulfenite is identified by XRD in several drill core samples (Appendix 11.3) from the Steeple Rock district, it was not found in petrographic studies. However, elemental analyses of a few samples indicate several hundred ppm of molybdenum, suggesting that wulfenite may indeed occur in the district. Wulfenite is typically a secondary, oxidized mineral.

4.1.2 Gangue mineralogy

4.1.2.1 Quartz, SiO_2 —Quartz is the most common mineral in the Steeple Rock district (Appendix 11.2, 11.3) and is the only mineral phase deposited throughout all periods of alteration and mineralization. Multiple, complex combinations of various textures, as defined by Dowling and Morrison (1989), occur throughout the Steeple Rock district. White, coarse-grained, and barren quartz veins are referred to as buck or bull quartz and rarely contain any impurities. Buck quartz may overlie rich gold-silver deposits, such as along the East Camp fault. Comb quartz, consisting of large, euhedral white to colorless to purple (amethyst) quartz is typically barren of metal values in the Steeple Rock district. Spider quartz veinlets, also barren, commonly cut white to gray to green chalcedonic to microcrystalline quartz which is also barren of mineralization. Recrystallized chalcedony or amorphous silica occurs also as small turbid, spheroidal fragments interstitial to vein quartz and is locally associated with gold and silver assays. Locally these chalcedonic fragments form triple-point grain boundaries typical of recrystallized amorphous silica (Herrington and Wilkinson, 1992). Gold and silver in the Steeple Rock district is typically associated with banded (crustiform and coloform), rhythmically-layered, and breccia quartz, although quartz veins displaying these textures may on occasion be barren of gold and silver. Banded and rhythmically-layered quartz consists of hundreds of thin bands or layers of quartz interlayered with thin black bands or streaks of sulfides (pyrite, galena, chalcopyrite, and/or sphalerite; Fig. 3.6). Veins displaying this texture typically carry gold and silver. Multiple periods of brecciation,

cementation by quartz, and rebrecciation are characteristic of the gold, silver, and base-metal veins in the Steeple Rock district (Fig. 4.12). The best grades appear to occur in areas of greatest textural complexity where multiple generations of quartz, chalcedony, and other minerals were deposited.

In thin section, quartz typically occurs as clear, euhedral crystals containing numerous fluid inclusions and the crystals are locally fractured (Fig. 4.13). Sutured and overgrowth boundaries are common as is locally strained quartz with undulatory extinction, which may represent recrystallized chalcedony or amorphous silica (Fig. 4.13; Sander and Black, 1988; Herrington and Wilkinson, 1992). Quartz typically contains many fluid inclusions and some quartz contains larger concentrations of inclusions along the crystal edges than in the crystal cores (Fig. 4.13). Growth zones are rare.

Most quartz is white to colorless. Local staining and dissolution of impurities or large accumulations of fluid inclusions may alter colorless quartz to shades of brown and black. Amethyst quartz (purple) is locally common and is found in both barren and mineralized veins. Bladed quartz, pseudomorphed after bladed calcite, forming a lattice texture is also common locally, especially along the East Camp-Summit fault (Fig. 4.14).

All of these characteristics are consistent with an epithermal origin (Dowling and Morrison, 1989).

4.1.2.2 Calcite, $CaCO_3$ —Calcite is variable in distribution in the Steeple Rock district. Large, white to colorless to tan, bladed calcite occurs along the East Camp-Summit, Bluebell, and Norman King-Billali faults. Bladed calcite is commonly replaced by quartz (Fig. 4.15) and both are found throughout the various drill holes along these faults (Fig. 4.14). Bladed calcite and bladed quartz after calcite are indicative of boiling zones within modern geothermal fields; this process is further described in section 6.2.1.

Calcite is vertically zoned at the Summit mine. At the surface south of the Inspiration

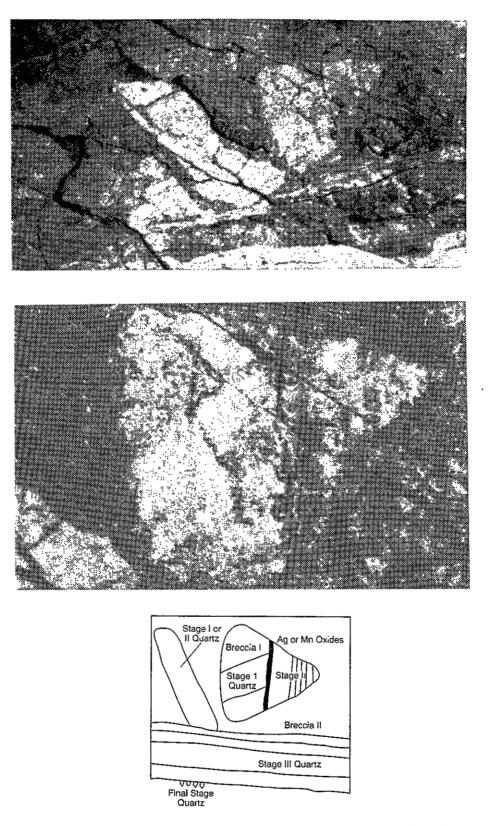

Figure 4.12—Photographs and sketch of brecciated quartz showing three periods of brecciation, from the East Camp vein.

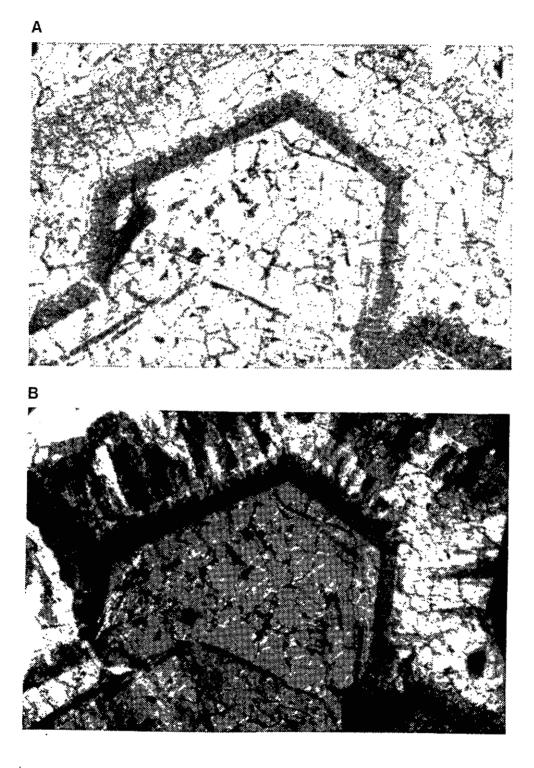

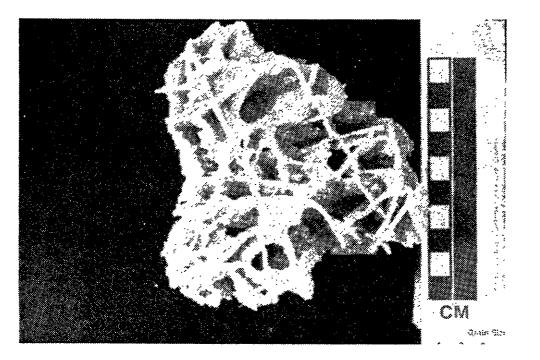

Figure 4.13—Photomicrographs of vein quartz with zones of small fluid and gas inclusions. Sample from the East Camp vein. Field of view is approximately 0.5 mm. A) Plane light. B) Crossed nicols. Note overgrowth of strained quartz with undulatory extinction.

183

Figure 4.14—Bladed quartz after calcite. Sample from the Summit vein near the Bank mine.

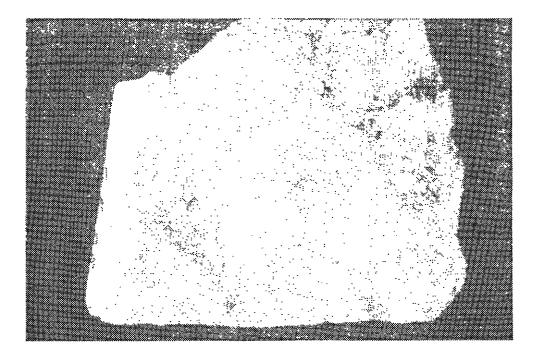

Figure 4.15—Bladed calcite in drill core. Sample is approximately 6 cm across and from drill hole B91-17 (depth of 358 m).

and Apex adits, the vein consists of approximately 50% calcite, mostly forming the center of the vein. The outer edges are quartz. In the Inspiration and Apex adits, the vein consists of less than 25% calcite, whereas drill holes immediately beneath the workings failed to intersect any calcite. However, north of the adits, bladed calcite is found in veins at depths of 358 m in drill hole B91-17, but constitutes less than 10% of the vein. It appears that in the Summit vein calcite decreases with depth.

Black calcite is common in the Goat Camp Springs and Foothills fault areas and is associated with manganese oxides. Southeast of the Summit mine, a zone of black calcite and manganese oxides crops out along the East Camp-Summit fault. Some calcite is intergrown with manganese minerals, whereas other calcite is coated with manganese minerals.

Elsewhere in the district, clear to white calcite is locally present but rarely in large concentrations, typically less than a few percent. Distinct rhombohedrons of calcite crystals are rare and most calcite is massive.

4.1.2.3 Pyrite, FeS_2 —Pyrite is the most abundant sulfide mineral in the Steeple Rock district. It occurs in all three stages of silicification and cementation of the vein deposits. It occurs in all five types of vein deposits and is disseminated throughout the host rocks. It is prevalent throughout most of the drill core and ranges in abundance from trace to 40% (Appendix 11.1). Pyrite grain size is variable from several microns to 1-2 cm, and typically occurs as euhedral to subhedral cubic crystals or irregular aggregates disseminated throughout the host rock. In the veins, pyrite occurs as (1) euhedral to subhedral cubic crystals or irregular aggregates disseminated throughout the vein quartz (Fig. 4.16); (2) streaks of aggregates of pyrite and other sulfides forming thin layers in the veins, or (3) irregular aggregates and intergrowths locally associated with other sulfides. An EDS x-ray spectrum of pyrite from the Center mine exhibits the purity of some pyrite (Fig. 4.17). In other sampled pyrite, solid inclusions and intergrowths of other minerals are present. Pyrite locally contains small inclusions of quartz, and fractures are locally healed by quartz, galena, sphalerite, and chalcopyrite. Pyrite also occurs intergrown with other sulfides and locally fills fractures in

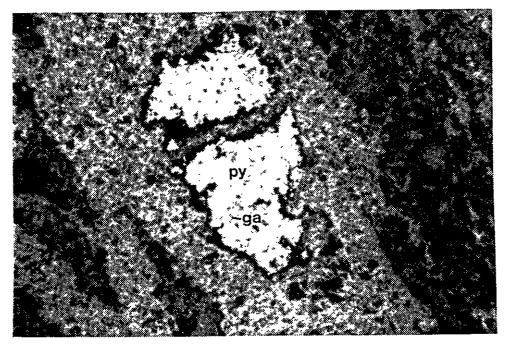

Figure 4.16—Irregular aggregate of pyrite within and cut by vein quartz. Note small inclusion of galena within pyrite grain. Field of view is approximately 0.5 mm. Sample is from the Alabama vein.

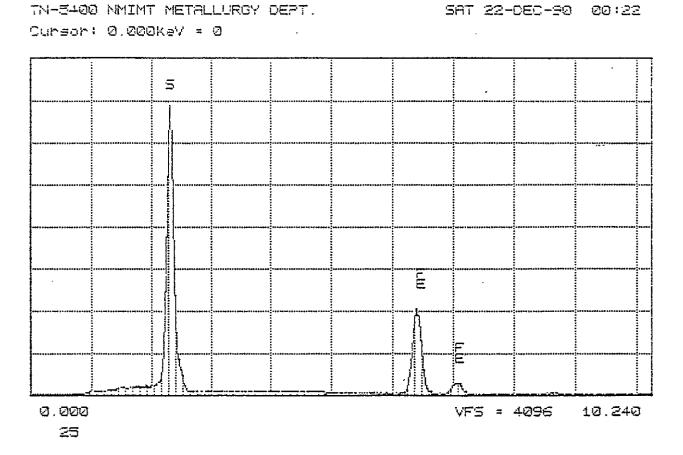

Figure 4.17—EDS x-ray spectrum of pyrite from the Center mine (20 kv).

chalcopyrite grains.

4.1.2.4 Adularia, KAISi₃O₈—Adularia is a low-temperature variety of K-feldspar that is characteristic of epithermal deposits (Hayba et al., 1985). It is difficult to identify in vein deposits of the Steeple Rock district because it is small in size and intergrown with quartz. In thin section, it resembles quartz and can be distinguished from quartz only by its biaxial optical figure. Most adularia is clear, free of mineral or fluid inclusions, and may exhibit cleavage, whereas most quartz is clear to cloudy, contains numerous mineral and fluid inclusions, and does not exhibit cleavage. Adularia appears to occur in mineralization stages 2 and 3. Its presence is confirmed by XRD (Appendix 11.3). Locally small veinlets of adularia and quartz cut across early deposited quartz. Adularia content in the veins is low—less than 5%.

4.1.2.5 Clays—Clay alteration near and within veins is common. Typically kaolinite with illite and locally illite/smectite occurs near the surface. Illite is common in the deeper portions of the veins. Areas with two or more veins are typically altered to quartz and illite between the veins. Chlorite is also common in the host rock and in breccia fragments. In the Carlisle and Center mines, primary chlorite occurs within the veins and is a guide to ore zones. However, crosscutting relationships indicate that chlorite precipitated before or after the sulfides. Typically illite/smectite and smectite/chlorite forms zones or halos surrounding the veins. More data and details on alteration follow in Chapter 5.

4.1.2.6 Fluorite, CaF_2 —Fluorite occurs as a gangue mineral in base-metal and goldsilver vein deposits along the Carlisle and Norman King-Billali faults. Small fluorite cubes and octahedrons, less than one millimeter across, occur in vugs and open spaces. The crystals are white to yellow to colorless and occur on quartz and sulfides. Locally, iron and/or manganese oxides coat the fluorite. Total fluorite concentrations rarely exceed 1-2% in these areas of the deposits.

Fluorite in the precious-metal veins is undesirable because the smelters in the area (Phelps Dodge and ASARCO) have very low limits on fluorine. Ores containing more than

0.5% may be rejected by the smelter. Fluorine is undesirable in the smelting process at local smelters and also is a pollutant to the atmosphere.

4.1.2.7 Manganese, titanium, and iron oxides—These oxides are relatively common throughout the vein deposits and altered rocks. They form alteration coatings and fracture fillings and locally form cement in the volcaniclastic sedimentary rocks. In thin sections, these oxides are typically prevalent and represent the oxidation of manganese, titanium, and iron-bearing minerals. Various manganese minerals are present: manganesite MnO, pyrolusite MnO₂, psilomelane (romanechite) BaMnMn₈O₁₆(OH)₄, and probably others. Titanium oxides present include rutile TiO₂, anatase TiO₂, leucoxene TiO₂, brookite TiO₂, pseudobrookite Fe₂TiO₅, and titanite (sphene) CaTiSiO₅ as determined by XRD (Appendix 11.3). Iron oxides include hematite Fe₂O₃, goethite FeO(OH), limonite 2Fe₂O₃·3H₂O, and ilmenite (Fe,Mn)TiO₃. Euhedral crystals are rare if even present. Irregular masses and aggregates of two or more oxides, locally with cores of the original mineral, are common.

4.1.2.8 Other gangue minerals—This section contains a short description of other minor gangue minerals that occur in the Steeple Rock district. They are arranged in alphabetical order and some minerals (designated by *) are suspect in their identification. Additional mineralogic work is needed.

Aragonite, $CaCO_3$ —Aragonite occurs in some deeper level veins and is confirmed by XRD.

Dolomite, $CaMg(CO_3)_2$ —Small (several millimeters) pink to tan to white rhombohedrons of dolomite occur in vugs and on quartz and other minerals. Its identification is confirmed by XRD. Rare veinlets of dolomite cut older veins. It is a late stage mineral.

Jarosite, $KFe_3(OH)_6(SO_4)_2$ —Jarosite has been confirmed by XRD in some samples (Appendix 11.3). It is fine-grained and occurs with iron oxides. It is probably a result of oxidation of pyrite.

Marcasite, FeS_2 —Some pyrite may be altered to marcasite. Marcasite has a strong anisotropy compared to pyrite, which is evident in some polished thin sections. Also some

XRD patterns suggest that marcasite may be present (Appendix 11.3).

*Pyrrhotite, $Fe_{1-x}S$ —Pyrrhotite may be present according to XRD data (Appendix 11.3). It is probably associated with pyrite and is not a major constituent.

Rhodochrosite, $MnCO_3$ —Rhodochrosite is confirmed by XRD in some veins. It is probably late stage.

4.2 Fluid Inclusion Studies

4.2.1 Sample selection and measurements

Fluid inclusion studies provide data on the temperature, composition, and pressure of the mineralizing and later fluids and the variation of these properties in space and time. There are five major assumptions which must be considered when interpreting fluid inclusion data (Roedder and Bodner, 1980):

- 1) The fluid trapped was a single, homogeneous phase at the time of trapping.
- 2) The cavity in which the fluid resides has not changed volume.
- 3) The fluid has not changed composition.
- 4) The effects of pressure are insignificant or are known.
- 5) The origin of the inclusions is known.

These assumptions and various tests for their validity are discussed by Roedder and Bodner (1980), Roedder (1984), and Shepherd et al. (1985) and were applied in this study where appropriate.

Samples for fluid inclusion microthermometric measurements were selected from vein quartz, fluorite veins, and sphalerite disseminated in quartz veins. Surface samples, samples from underground workings, and samples of drill core were used. Doubly-polished thick sections of vein material plus cleavage fragments of fluorite were examined according to methods described in section 1.5.6.

Inclusions were identified as primary, pseudosecondary, and secondary according to the criteria of Roedder (1984). Primary and pseudosecondary inclusions are difficult to find in many samples and any inclusions which did not adhere to the criteria of Roedder (1984) were assumed to be secondary. Microthermometric measurements were made on all three types of inclusions in order to better define the distribution of the measurements. Many inclusions, especially primary inclusions, are too small to measure last-ice melting temperatures; therefore salinities were not calculated for many inclusions.

Inclusions demonstrating evidence of leakage and necking down (Roedder, 1984; Shepherd et al., 1985) were not used in microthermometric measurements. Wherever possible, a statistically valid sample population of 30-40 inclusions was measured for each specific sample (Shepherd et al., 1985). However, the number varies because of lack of inclusions suitable for study or the variations in temperatures were small enough that a statistically valid sample population of fewer inclusions could be obtained. Many samples examined during the early stages of this study have a large number of measurements because of limited familiarity and expertise in the experimental procedures, and general trends of distributions of data for each type of inclusion which were required.

Fluid inclusions suitable for study are rare to absent in calcite, adularia, and malachite from Steeple Rock. The inclusions tend to be small (less than 3 μ m), rod shaped, and show evidence of necking. Therefore these inclusions are unsuited for microthermometric measurements.

Fluid inclusions are also rare to absent in the altered rocks, even in quartz veinlets. Where formed, the inclusions tend to be small (less than 5 μ m) and consist of either only liquid or liquid plus a small vapor bubble. These inclusions are difficult to impossible to obtain meaningful microthermometric measurements. Furthermore, studies have shown that fluid inclusions in silicified rocks within epithermal systems may not provide any meaningful data (Fournier, 1985a; Sander and Black, 1988). In the Steeple Rock district, it is sometimes difficult to determine the origin of the silica, much less determine the origin of the inclusions. Some of the quartz in the silica-altered zone may have been originally deposited as amorphous silica that was subsequently converted to chalcedony then to quartz. Much of the quartz in the intermediate- and clay-altered zone is probably either silica residue or recrystallized quartz. It is impossible to determine what stage of fluids the fluid inclusions represent: (1) during original deposition, (2) after crystallization, (3) during the time of deposition of amorphous silica that was later remobilized during the transformation to quartz, or (4) much later fluids (Fournier, 1985a). Therefore microthermometric measurements of fluid inclusions in the altered rocks were not made.

4.2.2 Characteristics of fluid inclusions

Three types of fluid inclusions are found in quartz, fluorite, and sphalerite: liquid plus vapor, liquid, and vapor. No daughter minerals were found in any inclusions examined. The most-abundant type of inclusions found are two-phase inclusions: liquid plus vapor. The vapor phase accounts for 5 to 30% of the total inclusion volume, using the visual estimation charts of Roedder (1984). The inclusions are suboval to irregular to prism shaped and range in size from less than 3 μ m to 100 μ m (Fig. 4.18). Most inclusions are less than 15 μ m. Many inclusions in fluorite retain a negative crystal shape (Fig. 4.19). The liquid and vapor inclusions are typically suboval to irregular in shape and less than 10 μ m. Some vapor inclusions may actually be two-phase inclusions with a liquid phase of less than 15%. However, because of their small size, it is difficult to determine with any certainty if any liquid was present (Shepherd et al., 1985).

Primary inclusions occur as isolated inclusions, small clusters, or planes of hundreds of inclusions along growth zones. Typically inclusions along growth zones are less than 1 μ m and not suited for microthermometric measurements (Fig. 4.13). Secondary inclusions occur as planes of tens to thousands of inclusions of all sizes along healed fractures.

Pseudosecondary inclusions occur as tens to hundreds of inclusions along healed fractures that terminate within the crystal, typically at growth zone boundaries and represent fluid trapped within fractures during the crystal growth (Roedder, 1984).

Fluid inclusions are common in quartz from the Steeple Rock district, although not all

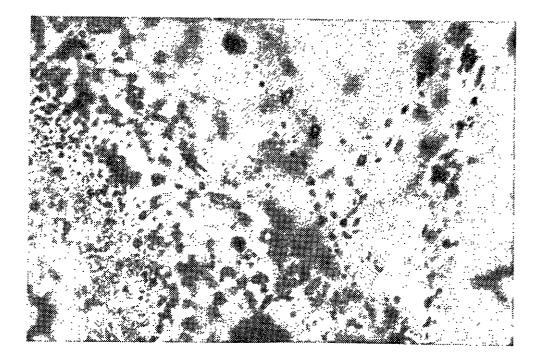

Figure 4.18—Photomicrograph of fluid inclusions in quartz. These inclusions are approximately 3 μ m in diameter.

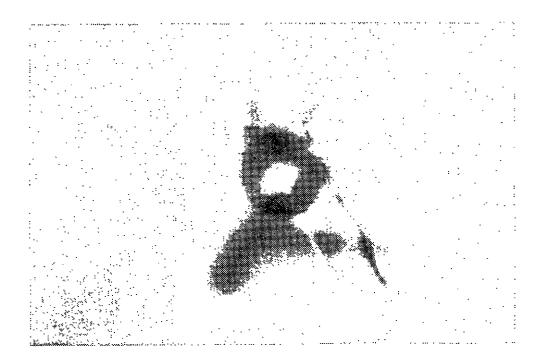

Figure 4.19—Photomicrograph of fluid inclusion retaining a negative crystal shape in fluorite. Fluid inclusion is approximately 15 μ m across.

samples contain primary inclusions suitable for microthermometric measurements. Fluid inclusions are rare in sphalerite, especially where the sphalerite displays chalcopyrite disease (i.e. small solid mineral inclusions of chalcopyrite within larger sphalerite crystals). The sphalerites examined in this study typically are honey yellow to light brown in color. Dark brown to black sphalerite is too opaque to allow examination of fluid inclusions. Most fluorite contains numerous secondary inclusions and lesser numbers of primary inclusions.

Only a few samples contained coexisting liquid-rich and vapor-rich inclusions, but these inclusions were typically too small to be measured. Also it was difficult to determine if these inclusions were of the same fluids; most were secondary inclusions. If liquid-rich and vapor-rich inclusions from the same generation of fluids are present in a sample, this is interpreted as evidence of boiling (Roedder, 1984; Shepherd et al., 1985). Fluid inclusion evidence for boiling in the Steeple Rock samples examined is inconclusive.

Geochemical analyses of the gas and liquid composition of the inclusions are beyond the scope of this project. A Masters thesis by Randy Ruff (NMIMT Geoscience Department) indicates that gases indicative of magmatic fluids, such as H_2S , HS, CO₂, and He, are present in some veins in the district (Ruff, 1993; Ruff and Norman, 1991). These gases are found in other epithermal deposits (Ruff and Norman, 1991).

4.2.3 Microthermometric measurements

5

Temperatures of homogenization (Th) and last-ice melting temperatures (Tm) were measured on fluid inclusions from various parts of the district. Temperatures of homogenization are reported uncorrected for pressure and are assumed to represent temperature of entrapment, which is close to temperature of formation. Pressure corrections are assumed small to none because the minerals were deposited near the surface (see section 6.2.2). The salinity is reported in terms of equivalent weight % NaCl and is obtained by measuring the last-ice melting temperature and converting it to eq. wt. % NaCl by using the equation (Roedder, 1984):

$$W_s = 0.00 + 1.769580 - 4.2384 \times 10^2 \text{ O}^2 + 5.2778 \times 10^4 \text{ O}^3$$

where W_s = equivalent weight % NaCl (eq. wt. % NaCl), O = the freezing point depression (last-ice melting) in °C. The data are graphed for each group of mines in Appendix 11.7 and summarized in Tables 4.1, 4.2, and 4.3 and Figures 4.20, 4.21, and 4.22.

4.2.3.1 Quartz—Quartz is the most common mineral in the veins and was deposited continuously before, during, and after sulfide mineralization. Quartz is associated with the sulfide minerals and contains fluid inclusions, and therefore it is assumed that microthermometric measurements of quartz associated with sulfide minerals represents similar temperatures and chemistries as the sulfide minerals. Over 700 primary and secondary inclusions were measured for this study to determine (1) temperature of formation of the various mineral stages, (2) temperature zonations within the district (laterally, vertically, and with time), and (3) composition of the mineralizing fluids (salinity).

Most of the inclusions examined for this study were stage 2 mineralization— i.e. the sulfide deposition event. Samples of quartz deposited prior to the sulfide minerals (stage 1 mineralization) did not contain fluid inclusions large enough for microthermometric measurements. The inclusions, where present, were either too small (< 1 μ m in diameter) or were necked inclusions and could not be measured. Some of the stage 1 quartz exhibits textures characteristic of original chalcedony or amorphous silica and fluid inclusion data is meaningless (Sander and Black, 1988).

Several samples of quartz from stage 3 mineralization contained some fluid inclusions suitable for measurements, but microthermometric measurements were similar to those of stage 2 mineralization (Table 4.1). Inclusions were found in one sample of quartz crosscutting acid-sulfate alteration (#341) and temperatures of homogenization were between 190 and 357°C. The origin of these inclusions is unknown but fluid inclusion data support a similar epithermal origin as the epithermal vein deposits.

Locally quartz occurs in the fluorite veins; however, samples of this late stage quartz did not contain any fluid inclusions that were suitable for measurements. Late stage quartz

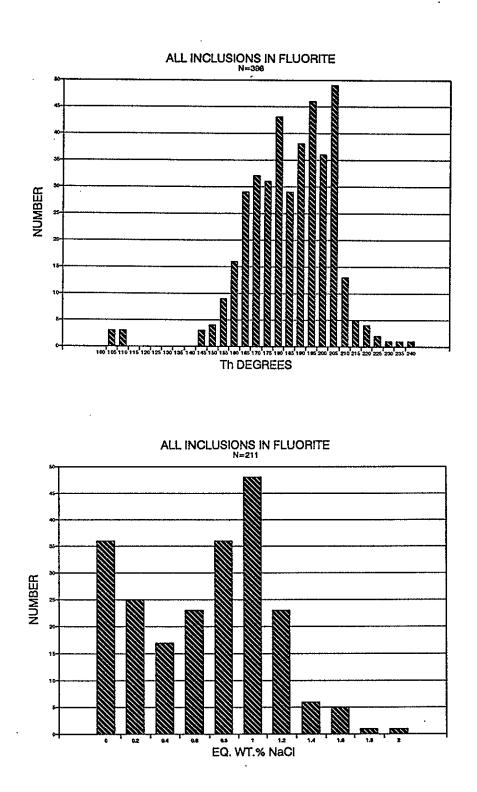

Figure 4.22—Histograms of temperatures of homogenization (Th) and salinities of fluid inclusions in fluorite.

crystals from the base- and precious-metal vein deposits were also examined, but no fluid inclusions were found.

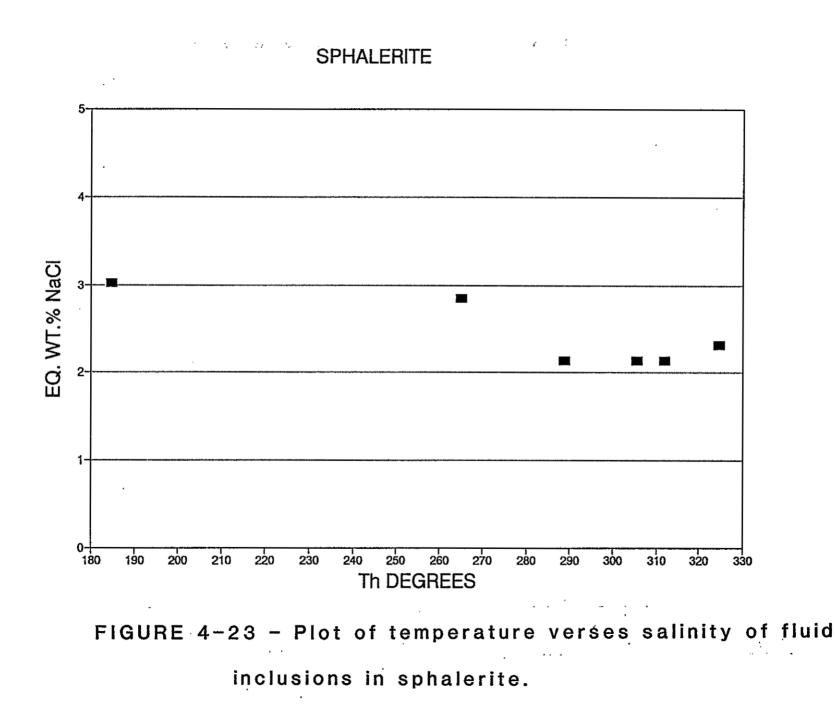

Therefore this study is restricted to three types of quartz: (1) stage 2 mineralization, (2) stage 3 mineralization, and (3) one sample of vein quartz crosscutting the acid-sulfate alteration.

The highest temperatures of homogenization are in quartz samples from drill core at the Carlisle and Center mines. Temperature increases with depth (Appendix 11.7). The surface samples from the Carlisle fault area typically contained fluid inclusions with temperatures of homogenization higher than elsewhere in the district. The next-highest samples were from along the East Camp fault and in the Alabama-Imperial area.

Plots of primary and secondary inclusions in quartz are similar and probably represent similar fluids (Appendix 11.7); therefore, all data were combined. A normal distribution of temperature of homogenization of all samples exists (Fig. 4.20). Salinities of all quartz samples are less than 5 eq. wt. % NaCl (Fig. 4.20). The higher salinities are from samples at depth in the Carlisle-Center area.

4.2.3.2 Sphalerite, (Zn,Fe)S—Sphalerite is the only ore mineral which occurs in the base-metal and gold-silver veins that contains visible fluid inclusions. Fluid inclusions in sphalerite are probably most representative of the ore-bearing fluids. However, only 27 fluid inclusions in sphalerite from three sample sites were measured. More than 20 polished sections were examined and most sphalerites did not contain any primary fluid inclusions.

Two distinct populations of fluid inclusions are identified (Table 4.2, Fig. 4.21). The primary inclusions have an average temperature of homogenization of 285°C (range 231.8°-324.6°C) and an average salinity of 2.4 eq. wt. % NaCl (range 2.1-3.0%). Secondary inclusions have an average temperature of homogenization of 153.8°C (range 116.5°-184.8°C) and an average salinity of 1.1 eq. wt. % NaCl (range 0.7-1.4%). Two distinct populations are obvious on a temperature vs. salinity plot (Fig. 4.23). The fluid inclusions in the Center mine ore have the highest temperatures of homogenization (300–340°C; Appendix

· 5.

-

11.7).

Fluid inclusions are rare in sphalerites that display chalcopyrite disease. The origin of chalcopyrite disease in epithermal deposits is best attributed to replacement by copper after formation of sphalerite or as epitaxial growth, as previously discussed in section 4.3.1.3. Fluid inclusions from both types of sphalerites (i.e. with and without chalcopyrite disease) were used in microthermometric measurements for this study, but only a few samples with chalcopyrite disease contained any usable fluid inclusions. No differentiation on the basis of presence or absence of chalcopyrite disease could be detected and, for the purposes of this study, it is suggested that chalcopyrite disease has no effect on fluid inclusion analyses. However, because of the small number of measurements, this hypothesis needs to be confirmed.

The highest temperatures of fluid inclusions come from samples from the Center mine. Samples from drill hole B91.17 (Summit-Bank properties, East Camp-Summit fault) contain numerous secondary inclusions of lower temperature and salinity. Temperatures of homogenization from all three sample sites are similar, therefore no temperature zonations or differences can be inferred.

4.2.3.3 Fluorite, CaF₂—Fluorite occurs in veins in the northern and western portions of the district and as late stage mineralization in the Center mine. Almost 400 fluid inclusions were examined in polished sections and cleavage fragments (Table 4.3). Two types of inclusions are identified in thin sections: primary and secondary inclusions (Table 4.3, Fig. 4.22). The primary inclusions have an average temperature of homogenization of 181°C (range 103-239°C) and salinity of 0.5 eq. wt. % NaCl. The secondary inclusions have an average temperature of homogenization of 184°C (range 102-239°C) and a salinity of 0.8 eq. wt. % NaCl. The difference in inclusion type does not account for the bimodal population. Both types of inclusions are treated in this report as one population of a similar fluid because the temperatures of homogenization and salinities overlap. As will be discussed later, this bimodal population is probably a result of either district zoning or two or more centers of fluorite mineralization (see section 6.3).

The highest temperature of homogenization come from fluorite in the Goat Camp Springs, Luckie, and Forbis mines. The lowest temperatures are from the Center and Black Cat mines and drill hole BC1 (Table 4.3; Appendix 11.7).

4.3 Geochemistry and statistical analyses of vein deposits

Several companies provided geochemical analyses of production shipments, surface sampling programs, and drill core sampling (Table 4.4). Numerous unpublished reports on file at NMBMMR also contained similar data. Three data sets were chosen for statistical analyses in order to better characterize these deposits. The data include production data from the Center mine (R&B Mining Co.), surface geochemical sampling data from the Carlisle (Weaco Exploration, Ltd.) and Alabama mines (Great Lakes Exploration Co.). These three data sets were chosen because they include multi-element analyses of numerous samples and data on methods of sample collection and analyses were available.

The purposes of this study are (1) to characterize the geochemistry of the deposits, (2) identify any pathfinder elements to aid in exploration for precious- and base-metal deposits in the district, and (3) identify and characterize any possible metal zonations. The data sets cannot be combined because different elements were analyzed by different laboratories and the samples were collected for different purposes by different people.

Correlation coefficients and factor analysis of the chemical data were performed using MSTAT (Rockware, Inc., 1992a) and SPSS (Nie et al., 1975), using raw data and standard matrices. Correlation coefficients are measures of the linearity or correlation between two variables. Typically correlation coefficients greater than 0.4 are significant (dependent upon number of samples) and correlation coefficients greater than 0.8 exhibit strong correlation between the two variables. Factor analysis is a statistical method that reduces a set of numerous variables to a lesser number of mutually uncorrelated factors which may be related to similar origins or sources. Factor analysis also identifies the minimum number of

.

variables necessary to account for the variation (% variance) in a data set.

4.3.1 Center mine

Chemical assay data of ore shipments from the Center mine were combined and the data are summarized in Table 4.5. The assays are from splits of ore shipments from the Center mine which were collected and analyzed by ASARCO laboratories. Periodically additional gold and silver assays were performed on some shipments by other laboratories and the duplicate analyses typically agreed. Correlation coefficients and factor analysis are in Tables 4.6 and 4.7.

Unfortunately, these data cannot be utilized in determining possible metal zonation because most shipments from the Center mine represent mixtures of different orebodies from throughout the mine. The miners were forced to mix high-grade with low-grade ore to maintain a constant shipment. Also the miners mixed high-fluorine with low-fluorine ore to keep fluorine concentrations below maximum standards set by ASARCO.

Statistical analyses of these data confirm a significant correlation between gold and silver and a strong correlation between lead and zinc (Fig. 4.24). Factor analysis confirms this correlation. Also factor analysis provides additional information. Factor group 1 indicates correlation between copper, zinc, lead, iron and a negative correlation with silica. This association is confirmed by field observations; copper, lead, and zinc minerals are associated with a decrease in quartz. Factor group 2 indicates a correlation between calcium and fluorine which corresponds to the late stage fluorite mineralization. Factor group 3 indicates a correlation between gold, silver, alumina, and negative correlation with silica. This corresponds to the association of gold and silver with illite, chlorite, and perhaps adularia. Note that 56.4% of the variation in the data is attributed to factors 1, 2, and 3. Factor group 4 indicates a correlation between arsenic and iron. This suggests that antimony, arsenic, and iron are either late stage and not associated with the precious and base metals or are remobilized by

subsequent supergene alteration and oxidation. This is supported by occurrence of iron oxides and mimetite coatings. Note that 73.7% of the variation in the data is attributed to Factors 1, 2, 3, 4, and 5.

4.3.2 Carlisle mine

Weaco Exploration Ltd. collected samples on a 100 m spaced grid at the Carlisle mine. Rock chip samples were collected at each location over approximately 0.5 m^2 and analyzed for a number of elements. Areas of mine tailings were not sampled. The data are summarized in Table 4.8. Correlation coefficients and factor analysis are summarized in Tables 4.9 and 4.10.

Statistical analyses confirm a strong correlation between gold and silver, lead and zinc, and bismuth, cadmium, zinc, and lead (Table 4.9; Fig. 4.25). These associations and other correlations are confirmed by factor analysis. Factor group 1 indicates a strong correlation between calcium, aluminum, nickel, cobalt, manganese, vanadium, phosphorus, lanthium, magnesium, titanium, sodium, and negative correlation with arsenic and molybdenum. This group most likely represents gangue and alteration mineralogy, because these elements are common to gangue and alteration minerals found at the Carlisle mine. Factor group 2 consists of lead, zinc, bismuth, and cadmium. Factor group 3 consists of gold, silver, manganese, and vanadium. Factor group 4 consists of arsenic, iron, and chromium. Factor group 6 consists of copper and calcium. The other factor groups are less important. The associations represented by factor groups 4 and 6 may be related to mobilization by supergene alteration and oxidation, because these elements are found in supergene minerals at the Carlisle. Iron and copper staining and chalcanthite are common along pit and adit walls and were deposited recently by acid mine water. The separate associations of gold-silver and lead-zinc represented by factor groups 2 and 3 are confirmed by field and production data. The veins in the upper levels of the Carlisle consist of a gold-silver (low base-metals) ore shoot and a parallel lead-zinc-copper (low gold and silver) ore shoot. The lack of a strong

correlation of copper in factor group 3 is also confirmed by field and geochemical evidence. In recent weathering, rainwater reacts with pyrite and other sulfides to form acidic water which accumulates and locally drains from the Carlisle mine. The acidic water tends to dissolve pyrite and chalcopyrite before galena and sphalerite. Thus the waters are more concentrated with iron and copper (J. McLemore, unpubl. report, March 1993).

Geochemical concentration maps of the various metals and pathfinder elements were prepared. These maps indicate that gold and silver anomalies occur along the Carlisle fault. A geochemical concentration map of arsenic values reported for each rock chip sample reveals a halo of slightly elevated arsenic concentrations over the Carlisle orebody (Fig. 4.26). This suggests that arsenic may act as a pathfinder element; this needs to be confirmed by additional studies. No other zonations of metals could be detected.

4.3.3 Alabama mine

Great Lakes Exploration Co. collected and assayed samples from the surface along the veins and faults in the Alabama mine area (Fig. 4.27). Channel samples comprised of rock chips from traverses 1 to 2 m long were collected at each location. The data are summarized in Table 4.11. All samples were analyzed for gold, silver, arsenic, antimony, mercury, and fluorine by Skyline Analytical Laboratory; 19–20 samples were also analyzed for major and trace elements by XRF by NMBMMR (Appendix 11.6). Correlation coefficients and factor analysis are in Tables 4.12 and 4.13.

Statistical analyses of these data confirm a strong correlation between gold and silver and copper, lead, and zinc (Fig. 4.28). Factor analysis confirms this correlation (Table 4.13). Factor 1 consists of SiO₂, F, As, Sb, Fe₂O₃, CaO, MgO, P₂O₅, Ba, and Zr which reflects original and alteration mineralogy, because these elements occur in the original host rock and altered minerals. Factor 2 consists of Au, Ag, Pb, F, and Hg. Factor 3 consists of Cu, Pb, Zn, Sb, and V. The remaining factors reflect original and alteration mineralogy. Note the lack of any arsenic halo over the Alabama mine in Figure 4.27.

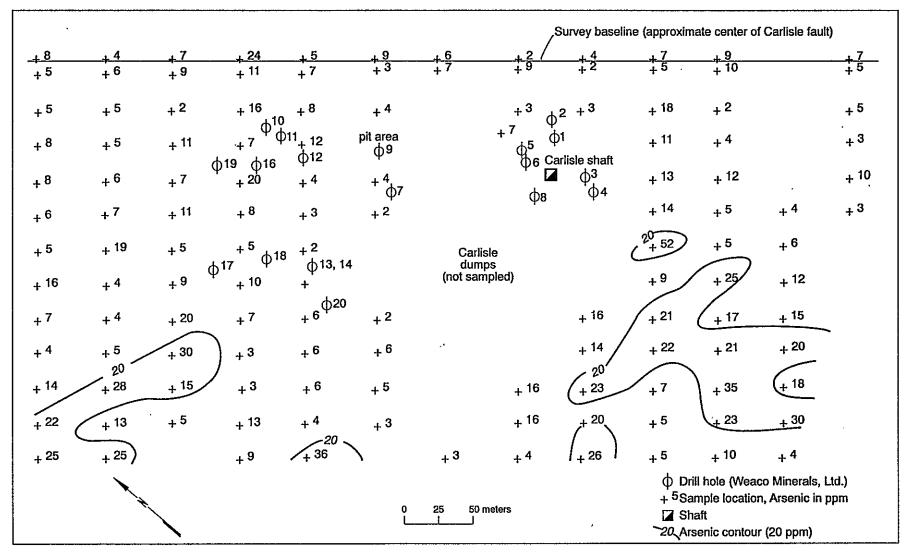

Figure 4.26 - Geochemical concentration map of arsenic at the Carlisle Mine. Weak arsenic anomalies (> 20 ppm As) overlie projected ore shoots.

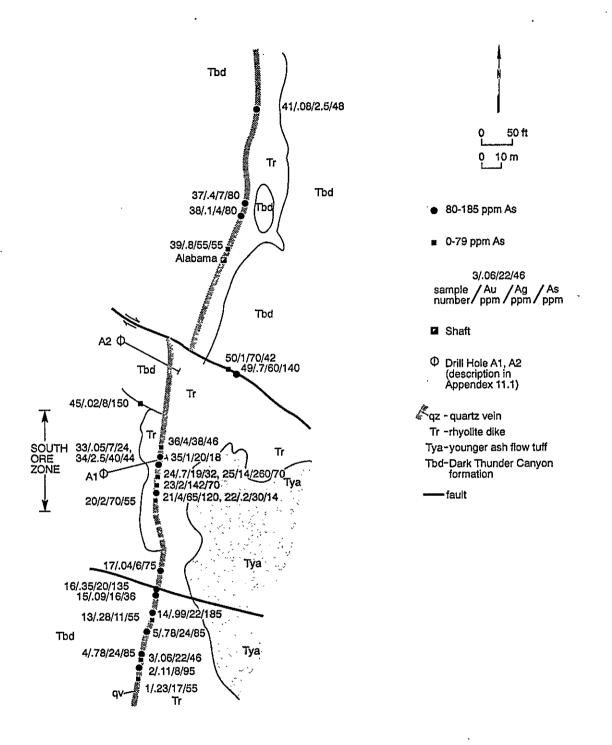

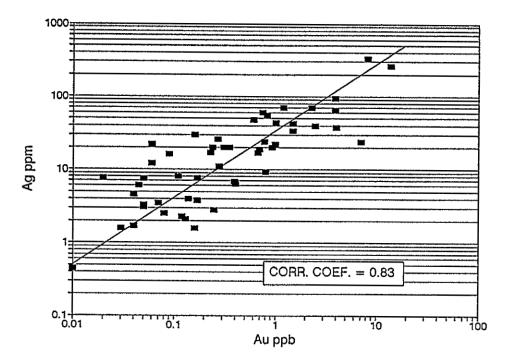

Figure 4.27-Geochemical concentration map of arsenic at the Alabama Mine area. Geology and samples by T. Quigley (1991). South ore zone defined by outcrop assays and limited subsurface data.

4.3.4 Summary of geochemical and statistical analyses

The veins in the Steeple Rock district are enriched in silica (>75%) and provide excellent silica flux for local smelters. Although anomalously high concentrations of copper, lead, and zinc occur in most ore shoots (section 3, Tables 4.5, 4.8, 4.11), the base metals are higher in the base-metal veins (>2% Pb, >2% Zn, and 0.4–1.5% Cu) than in the gold-silver veins (<0.5% combined Cu, Pb, Zn). Impurities such as aluminum, antimony, arsenic, mercury, bismuth, and cadmium are typically below limits set by the local smelters. However, fluorine and calcium concentrations are variable in all types of deposits and may exceed local smelter limits. Some ore shipments from the Center, Laura, Carlisle, and Summit mines were rejected or penalized by local smelters because of high concentrations of calcium or fluorine. Locally, elevated levels of bismuth, especially at depth, have resulted in penalties by the smelters (i.e. Center mine).

The Steeple Rock vein deposits are characterized by a strong correlation between lead and zinc and, to a lesser extent, between gold and silver. These correlations exist in both base-metal and gold-silver veins and are apparent in additional assay and production data of most mines besides the three data sets presented here. Statistical analyses of various data sets from the Steeple Rock district indicate that gold and silver exhibit little or no correlation with copper, lead, and zinc. Furthermore, statistical analyses indicate that copper exhibits little or no correlation with lead and zinc. This is a result of complex, constantly evolving chemical and physical conditions described in section 6.

Although typical pathfinder elements for precious- and base-metal deposits, such as arsenic, antimony, mercury, and bismuth, locally have strong correlations with specific precious or base metals in the Steeple Rock district, no definite pattern exists district-wide except for arsenic. A pathfinder is a relatively mobile element that is associated with an element of economic interest, but the pathfinder is more easily found because it forms a broad halo surrounding the element of interest. Some studies suggest that a halo of elevated arsenic concentrations may occur over mineralized deposits, such as the Carlisle (Fig. 4.26) and

Summit (Don Burton, NovaGold Resources, Inc., pers. comm. April 1993) mines. However, arsenic halos were not observed at the Alabama mine (Fig. 4.27). These data suggest that locally pathfinder elements should be used but with caution. The best geochemical pathfinders for gold-silver deposits in the Steeple Rock district are gold and silver. It should also be noted that most samples containing anomalously high concentrations of gold and silver typically also contain elevated concentrations of copper, lead, and zinc (Appendix 11.6). However, not all samples containing elevated copper, lead, and zinc contain detectable gold or silver.

Analyses of the various geochemical data indicate that little or no chemical zonations exist laterally. Locally, in some mines, precious and base metals either decrease or increase in concentration with depth (see mine descriptions in Chapter 3: Laura, Alabama). Decrease in precious metals and increase in base metals with depth suggests the bottom of the ore shoot has occurred and either the mine is depleted in precious metals or parallel blind veins may occur, as at the Carlisle and Center mines. Increase in precious metal concentrations with depth also could suggest that additional ore may occur below the present level of mining (see section 3).

4.4 Economic Potential

A secondary objective of this study was to evaluate the district in terms of economic resource potential of all possible commodities. This section includes evaluations and brief discussions of various commodities that occur or were thought to occur in the Steeple Rock district.

4.4.1 Gold and silver

Known resources of gold and silver have been delineated by drilling along the Jim Crow-Imperial and East Camp-Summit faults (Queenstake and Biron Bay). Additional drilling along the Norman King-Billali fault indicates additional ore exists. These resources will become more attractive with an increase in the price of gold and silver. The resource potential for epithermal gold-silver veins elsewhere in the Steeple Rock district is excellent but will require extensive drilling and assaying to locate such deposits. Much of the district remains unexplored at depth.

Drilling has occurred between the Carlisle and Center mines, along the East Camp, Summit, and Blue Bell veins, in the Jim Crow and Imperial mines area, at the Alabama mine, and locally one or two drill holes were placed elsewhere in the district. Many areas have not been adequately drilled, such as the Laura-Smuggler veins, New Year's Gift vein, Mt. Royal mine area, west of the Carlisle mine along the Carlisle fault, at the Ontario mine, along the Apache and Blue Goose faults, and in the Goat Camp Springs and Foothill fault areas (Map-2). Of over 60 mines in the district, only seven mines exceeded depths of 100 m (Alabama, Carlisle, Center, East Camp, Laura, Norman King, and Twin Peaks mines).

• • .

Blind ore shoots which do not crop out at the surface but are parallel to outcropping gold-silver veins are common and are similar to those found at the Carlisle mine. Many ore shoots in the district do not crop out at the surface (such as the Center vein).

Ore is commonly associated with inflections and changes in strike and dip of the faults. Some ore shoots, especially in the East Camp area, are indicated at the surface by pods of barren, white quartz, referred to as quartz blowouts by early miners (Griggs and Wagner, 1966; Gillerman, 1968).

Mineralogical and chemical zoning may be important and is discussed in more detail in section 6.3. Copper-silver veins locally grade into precious metal veins (i.e. Blue Bell mine) and may offer viable exploration targets. Fluorite veins may also grade with depth to gold-silver veins and should be examined by drilling (i.e. Goat Camp Springs area). Geochemical sampling at the Carlisle and Summit mines suggests that an arsenic halo may exist over some orebodies. Therefore surface geochemical sampling around outcropping structures may also provide drilling targets for blind veins. However, geochemical sampling at the Alabama did not show an arsenic halo; so such studies may not aid in exploration everywhere in the district. The resource potential in the Steeple Rock district for undiscovered disseminated highsulfidation gold deposits associated with the acid-sulfate alteration is also excellent, but unproven. Assays of some samples are indicative of disseminated gold deposits (Raeburn Hills; Telephone Ridge area; Saddleback Mountain; Appendix 11.6), but drilling in some of these areas failed to delineate any deposits.

Some potential may also exist for disseminated gold in brecciated and silicified rhyolite intrusions (Wahl, 1980). Areas within the Apache Box intrusion contain anomalously high concentrations of gold (Wahl, 1980; Briggs, 1982).

4.4.2 Base metals

The potential for base-metals vein deposits is excellent along the Carlisle fault; however, drilling is required to locate additional deposits. The base-metals concentration increases with depth in many precious-metals deposits (Summit, Jim Crow-Imperial, Alabama, Laura, Carlisle, Center veins) and may offer some potential by-product production as in the past.

The pervasive alteration and regional proximity to several major porphyry copper deposits (Fig. 1.1; Morenci, Tyrone, Chino, Safford) have enticed exploration geologists to the district for years. The known copper porphyries in the area are Laramide in age (56–73 Ma; Titley, 1982), but the Steeple Rock host rocks are younger than Laramide-age rocks. Some geologists have suggested the possibility of Tertiary porphyry deposits at depth on the basis of alteration and epithermal veins exposed at the present surface. But deep drill holes (Bitter Creek BC1 hole, 762 m and Biron Bay drilling; Appendix 11.1) have failed to penetrate any copper porphyry deposits or Laramide-age rocks. Although it is possible a copper porphyry may occur at depth, it is unlikely that it would have undergone supergene enrichment and is most likely uneconomic because of low grades and extreme depths.

4.4.3 Fluorite

Fluorite veins are common in the western and northern parts of the Steeple Rock district, especially near rhyolite intrusives. Fluorite also has been produced in the past. Fluorite is the principle source of fluorine, which is a vital raw material in the chemical and metallurgy industries. The United States imports a large amount of fluorite (McAnulty, 1978; U.S. Bureau of Mines, 1992).

The fluorite deposits in the Steeple Rock district are small and contain impurities such as quartz, calcite, and manganese. These deposits are uneconomic compared to foreign sources. However, should local fluorite deposits become desirable, the fluorite deposits in the Steeple Rock district should be re-examined by drilling and detailed mapping for potential use.

4.4.4 Manganese

Manganese veins and fracture coatings are common throughout the Steeple Rock district and one deposit produced some ore. However, the manganese veins in the Steeple Rock district are small and contain impurities such as country rock, quartz, fluorite, calcite, and iron oxides. These deposits are not economic under current economic conditions.

4.4.5 Alunite

Alunite is a potential source of aluminum and has been mined in several places in the world for its aluminum content (Hall, 1978). The alunite deposit at Saddleback Mountain contains the largest amount of alunite in New Mexico with an estimated resource of 6 million tons of potential resources of 30% alunite (Hall, 1978). However, the alunite deposits in the Steeple Rock district contain impurities such as quartz, pyrite, and clay. Currently, the alunite deposits in the Steeple Rock district, as in other localities in the United States, are uneconomic. Nevertheless, as the United States imports all of its required aluminum and if foreign supplies should be threatened or exhausted, the potential in Steeple Rock would change.

4.4.6 Clay

Clay is an important industrial mineral used in a variety of industrial and chemical uses. Kaolinite is particularly important in manufacture of paper, ceramics, bricks, and other uses. The acid-sulfate altered areas in the Steeple Rock district have an unknown potential for clay, especially kaolinite. Although impurities such as quartz, alunite and pyrite occur in much of the altered areas, locally small areas of relatively pure clay occur. Exploration and testing is required to determine if the clay deposits in the Steeple Rock district are economic.

4.4.7 Decorative Stone

At least two quarries (near Telephone Ridge and Bitter Creek area) were operated for decorative or building stone. Production is unknown, but the quarries are small, and thus production was probably small. The leisegang-banded rocks are quite suitable for decorative stone. The potential markets would be Tucson, Phoenix, and El Paso. Transportation costs would be high and prohibit large-scale exploitation, although resources are probably extensive and quarrying is feasible.

4.4.8 Beryllium

Several fluorspar mines and prospects were examined for beryllium (Meeves, 1966). Concentrations were low. Beryllium was not analyzed for in this study. It is possible that local concentrations of beryllium could exist with fluorite veins or with the acid-sulfate alteration. However, tonnage is probably small and therefore the potential for beryllium is probably low.

4.4.9 Molybdenum

It has been suggested by some explorationists that a porphyry molybdenum deposit

could occur at depth in the Steeple Rock district. Certainly the regional alteration and epithermal mineralization is consistent with a deep porphyry molybdenum deposit. Many of the rhyolites from the district are similar in chemistry to granitic molybdenite source rocks (i.e. $\geq 74\%$ SiO₂, $\geq 4.5\%$ K₂O, $\leq 3.6\%$ Na₂O; Bornhorst, 1986). In addition, streamsediment samples from the area suggest elevated molybdenum values (Hassemer et al., 1983). Therefore, molybdenum was analyzed for on many samples throughout the Steeple Rock district (Appendix 11.4, 5, 6), but values are typically low. Porphyry molybdenum deposits are typically zoned and the sampling for this study was reconnaissance in nature and could easily miss a molybdenum anomaly. Therefore, the data available are inconclusive to determine the potential for a porphyry molybdenum deposit at depth. Additional drilling, geochemical and perhaps geophysical studies would be required, but are not viable under current economic conditions.

4.4.10 Uranium

The Steeple Rock district was first examined for the possibility of uranium resources in the 1950s, when the Carlisle mine was examined and determined not to be favorable for uranium deposits (R. B. Stroud, U.S. Atomic Energy Commission, PRR Report DEB-RRA-1169, January 11, 1954). During the 1970s volcanic rocks were of interest in uranium exploration and geologists once again examined the district with discouraging results.

The Steeple Rock district, part of the Silver City 1° x 2° quadrangle, was examined again during the NURE (National Uranium Resource Evaluation) program. Aerial radiometric reconnaissance survey of the Steeple Rock district delineated three minor uranium anomalies in and near the Steeple Rock district (Texas Instruments, Inc., 1978). These are best explained by uranium associated with intrusive rhyolites. Reanalysis of the aerial radiometric data indicates the area has low background levels of radioactivity (<2 ppm eU, Duval, 1988). Data from the stream-sediment sampling survey indicate average or below average values for uranium (less than 3 ppm; Sharp et al., 1978). During the course of field work a gamma-ray scintillometer was used sporadically to locate areas of anomalous radioactivity. A few rhyolite intrusives were slightly above background (up to three times background radioactivity). Samples analyzed for uranium were low (less than 15 ppm, Appendix 11.4, 5, 6). It is therefore concluded that the potential for uranium resources in the Steeple Rock district is low.

4.4.11 Tungsten

Several fluorspar mines and prospects were examined for tungsten (Trace, 1947) where up to 1-2% WO₃ was found locally with manganese oxides. A few stream-sediment samples in the northern portion of the area have anomolously high tungsten values (>100 ppm; Hassemer et al., 1983). Tungsten was not analyzed for in this study. There are not enough data to adequately address the resource potential for tungsten and additional geochemical analyses would be necessary to confirm any tungsten potential.

5. ALTERATION

5.1 Introduction

Alteration is a general term describing the mineralogic, textural, and chemical changes of a rock as a result of a change in the physical, thermal, and chemical environment in the presence of water, steam, or gas (Bates and Jackson, 1980; Henley and Ellis, 1983). The nature of the alteration depends upon (a) temperature and pressure at the alteration site, (b) composition of the parent rock, (c) composition of the altering (invading) fluids, (d) permeability of the parent rock, and (e) duration of the alteration process (Browne, 1978; Henley and Ellis, 1983). Recognition and genesis of alteration are important in mineral exploration and understanding the formation of ore deposits, because specific alteration types are associated with specific ore deposits. Furthermore, alteration halos surrounding ore deposits are typically more widespread and easier to recognize than some of the orebodies themselves (Guilbert and Park, 1986).

15,

Research by White (1955, 1981) established the now recognized association between epithermal mineral deposits and modern, active geothermal systems. Alteration assemblages associated with epithermal vein deposits are similar to alteration assemblages found in modern geothermal systems (Buchanan, 1981; Mitchell and Leach, 1991). Therefore analogies between modern geothermal systems and ancient epithermal deposits will aid in understanding the genesis of epithermal mineral deposits, such as those found in the Steeple Rock district.

Alteration can be classified and defined in many ways but most classifications are based upon mineral assemblages (Guilbert and Park, 1986). The term assemblage implies mutual equilibrium growth of mineral phases, whereas association implies that the mineral phases are only in physical contact. A number of terms are applied to various alteration assemblages. Deuteric alteration refers to the interaction between volcanic or magmatic rocks and magmatic-hydrothermal fluids during the cooling of the igneous rocks. A variety of alteration minerals may be produced. Propylitic alteration is the mineral assemblage consisting of epidote, chlorite, pyrite, quartz and carbonate minerals. Sericitic alteration is defined by

228

the dominance of illite, sericite, and/or muscovite. The major difference between these three K-micas is size: illite is a clay-size K-mica, whereas muscovite is larger. Sericite is of intermediate size. Some minor compositional differences also occur between the three minerals. Argillic alteration consists of kaolinite, smectite (montmorillonite clays), chlorite, and sericite. Advanced argillic alteration consists of kaolinite, quartz, alunite, pyrophyllite, and other aluminosilicate minerals. Silicic alteration is produced by the addition of silica, predominantly as quartz. Other terms are used for these and other alteration assemblages, but these are the classic alteration assemblages associated with epithermal vein deposits.

In modern geothermal systems, the alteration mineral assemblages reflect the composition of the prevailing fluid chemistry and it is common to describe the alteration assemblage according to fluid chemistry (Browne, 1978; Mitchell and Leach, 1991; Simmons et al., 1992; Reyes, 1990). There are three end member types of fluid compositions in modern geothermal systems: (1) alkali-chloride waters, (2) acid-sulfate waters, and (3) bicarbonate waters. Each type is characterized by specific mineral assemblages and other characteristics (Table 5.1). Mixing of these end member fluid types is common and more than one type of fluid can be present (Browne, 1978). Geothermal systems are dynamic, constantly changing, and rarely in equilibrium. Processes such as boiling, mixing, and condensation constantly occur in the geothermal system, producing a wide range of overlapping mineral assemblages and associations. For the purposes of this study, the alteration types are classified according to the type of fluids as indicated by the alteration mineralogy because it is typically difficult to distinguish between and map deuteric, propylitic, argillic, and advanced argillic alteration types in the epithermal deposits, especially in the Steeple Rock district.

Alteration of a parent rock occurs by several processes: (1) direct deposition, (2) replacement, (3) leaching, and (4) ejecta (Browne, 1978). All four processes are found in the Steeple Rock district. Direct deposition occurs by precipitation of new minerals in open spaces, such as vugs or fractures. Replacement occurs when one mineral is converted to a new mineral by fluids entering the rock. These two processes are common and depend upon

Table 5.1—Characteristics of geothermal fluids and associated alteration (modified from Simmons et al., 1992; Hedenquist, 1991; Henneberger and Browne, 1988; Henley and Ellis, 1983; Browne, 1978).

Fluid type	Alkali-chloride	Acid-sulfate	Bicarbonate	
Source of fluid	deep circulation	surfaced steam-heated condensate, locally with magmatic gases	condensation of steam and CO_2 into shallow groundwater	
Typical pH	6-7.5 (neutral)	<2.5 (acidic)	5–6	
Surface discharge	boiling spring, geyser, silica sinter	mud pools, collapse craters, hot springs	hot springs	
Typical alteration	propylitic, potassic	advanced argillic	argillic	
Mineral assemblage	chalcedony, quartz, albite, adularia, illite/smectite, chlorite, zeolites, epidote, calcite, pyrite	opal, kaolinite, alunite, diaspore, pyrophyllite, quartz, pyrite, sulfur	chalcedony, kaolinite, illite/smectite, chlorite, carbonates, pyrite	
Predominant fluid chemistry	chloride waters	sulfate waters	bicarbonate waters	
Form of alteration	direct deposition and replacement, ejecta	leaching followed by direct deposition and replacement, ejecta	direct deposition and replacement

.

permeability and duration of the process. Complete fluid/mineral equilibrium is rarely achieved because of these factors. Leaching and supergene enrichment occurs locally where steam condensate reacts to form acidic solutions by the oxidation of H_2S or CO_2 which then attacks the parent rock and dissolves primary or secondary minerals. Silica residue is a common result of leaching and is a spongy or vuggy altered rock consisting of predominantly quartz, iron and titanium oxides. Direct deposition or replacement may occur after leaching, thereby producing overlapping alteration types. Ejecta, hydrothermal brecciation, and hydrofracturing are another form of alteration where hot water and/or steam physically breaks the parent or even altered rock apart. If this forceful ejection of fluids occurs at or near the surface, hydrothermal eruptions of water, steam, and rock can occur. Silicification following the brecciation is common.

It is convenient to describe alteration in terms of intensity and rank. Intensity of alteration is a measure of how much alteration has occurred and can be estimated by determining the percentage of newly formed secondary minerals by visual estimation or more precisely by point counting (P. R. L. Browne, unpubl. report, Spring 1992). For example, a parent rock that has not been affected by any alteration would have zero intensity of alteration, whereas a parent rock in which all primary minerals have been replaced by secondary minerals would have an alteration intensity of 100%. In Appendix 11.2, each sample description includes a visual estimate of alteration intensity.

Alteration rank is based upon the identity of new secondary minerals and their significance in terms of alteration conditions such as temperature, pressure, and permeability. The intensity of alteration is independent of rank of alteration (Browne, 1978; Simmons et al., 1992). It is possible to have rocks with a high rank but low intensity (hot, impermeable zones) or other rocks of low rank, but high intensity (cooler, permeable zones; P. R. L. Browne, unpubl. report, Spring 1992).

Two types of alteration assemblages occur in the Steeple Rock district: (1) alkalichloride (propylitic to argillic to sericitic to silicic) and (2) acid-sulfate (advanced argillic).

However, the intensity and rank of alteration varies and there appears to be at least three distinct stages of alteration based on crosscutting relationships in examination of outcrops, drill core samples, and thin sections: (1) regional pre-mineralization, (2) localized synmineralization, and (3) regional post-mineralization. Several areas of intense acid-sulfate alteration are superimposed on regional alkali-chloride alteration. Furthermore, the relationship between the alteration and vein mineralization is complex. The remainder of this is chapter will describe the alteration assemblages in the Steeple Rock district.

5.2 Alkali-chloride alteration (propylitic-argillic-sericitic-silicic alteration) 5.2.1 Regional premineralization alkali-chloride alteration

. .

The most extensive type of alteration in the Steeple Rock district is an early regional pre-mineralization alkali-chloride alteration. This type of alteration has been briefly described as deuteric to propylitic alteration by Powers (1976) and Wahl (1980) and as argillization and chloritization by Biggerstaff (1974). The intensity and rank of alteration are variable and dependent upon lithology, permeability, and temperature.

This early alteration phase is typically characterized by a green to green-gray color of the altered rocks. Most rocks in the mapped area (Maps 1, 2) have been affected by this alteration; very few areas contain unaltered rocks. The mineral assemblage consists of essential chlorite (producing the green color), quartz, and pyrite and a variety of additional minerals depending upon host rock lithology, temperature, and composition of the fluids, including calcite, epidote, zeolites, adularia, sericite/illite, smectite, etc. Hematitization producing a brown to red-brown color masking the green color, is also common. The groundmass is altered to quartz and chlorite and feldspar phenocrysts are replaced by quartz, chlorite, adularia, and calcite.

One of the most important analogies between modern geothermal systems and ancient epithermal systems is the relationship of temperature and mineral assemblages. Numerous studies of modern geothermal systems have shown that certain minerals form in specific **MINERALS**

Figure 5.1-Temperature ranges of hydrothermal minerals in modern geothermal systems. Minerals listed are found in the Steeple Rock district.¹ These minerals occur in both alkali-chloride and acid-sulfate alteration assemblages. ² Pyrophyllite may occur on the surface associated with hot springs and geysers at approximately 100°C; temperature range given is for subsurface precipitation. Arrows indicate direction in which mineral can still be precipitated. Data from Reyes (1990), Elders et al. (1981), and Simmons et al. (1992)

temperature ranges (Reyes, 1990; Beaufort et al., 1992; Arnorsson et al., 1983; Henley and Ellis, 1983; Elders et al., 1981; Simmons et al., 1992). If modern geothermal systems and ancient epithermal systems are indeed analogous, then these studies can be used to reconstruct temperature ranges and variations in epithermal systems. Figure 5.1 is a summary of temperature ranges for hydrothermal minerals that occur in the Steeple Rock district.

This early alteration can be divided into three zones on the basis of mineral assemblages and inferred temperatures: (1) high temperature (>200°C), (2) intermediate to low temperature, and (3) low temperature (<200°C). The high temperature zone is less common in the district and is found along some epithermal veins and at depth. It consists of chlorite, quartz, pyrite, epidote, titanite (sphene), and a variety of other minerals such as calcite, adularia, and anhydrite. The intermediate to low temperature zone is the most extensive and consists of chlorite, quartz, pyrite, illite or illite/smectite, and a variety of additional minerals. The low temperature zone occurs in areas distant from faults and typically in less permeable rocks. It consists of chlorite and variable quartz, zeolites, pyrite, illite/smectite, smectite, kaolinite, and locally calcite. The intensity of alteration is typically low in the low temperature zone reflecting lower permeabilities.

Episodic periods of alteration probably occurred. Thin veinlets of quartz-chlorite (\pm pyrite), less than a millimeter wide, cut across chloritized andesite, but are subsequently offset by younger veinlets (Fig. 5.2). Quartz-sulfide veinlets also cut across older quartz-chlorite veinlets. Locally hematite-quartz veins cut across older alteration (Fig. 5.3). These cross-cutting relationships are found throughout the drill core and locally at the surface and in the Center decline.

5.2.2 Localized syn-mineralization

The most extensive alteration adjacent to and along faults in the district is silicification. Silicified zones vary in width along strike and some zones reach widths of several hundred meters. Locally parallel or bifurcating faults or veins occur that are separated

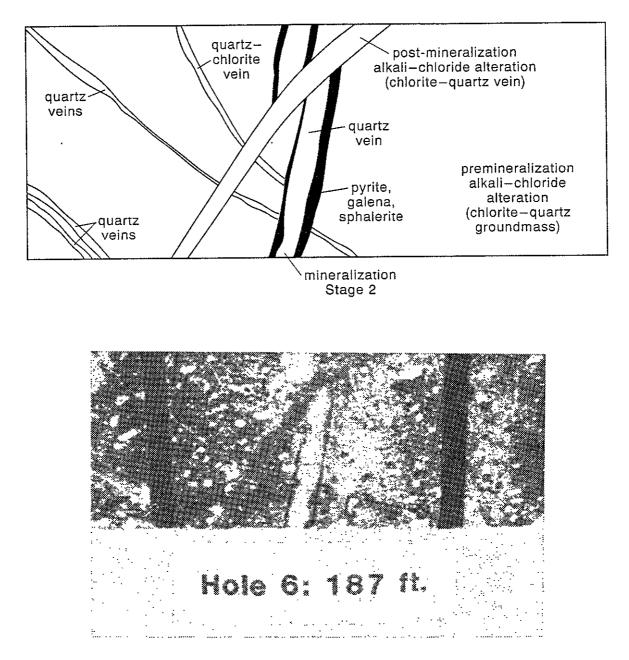

Figure 5.2—Photo and sketch of drill core showing complex alkali-chloride alteration. From USBM Drill Hole 6 at depth of 57 m (drilled at the 213 m level of the Carlisle mine). Distance between black ink lines is approximately 4 cm.

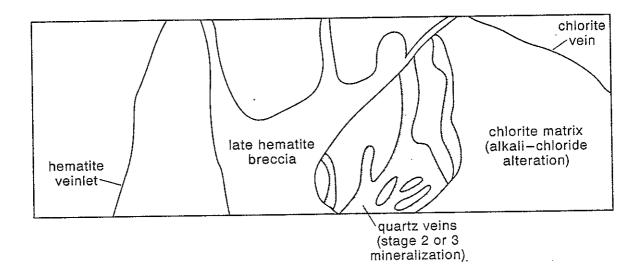

Figure 5.3—Photo and sketch of drill core showing hematite-quartz vein cutting older quartz-chlorite veins. From Jim Crow Drill Core J84–3 at depth of 71 m.

by silicified and locally brecciated host rock. Quartz occurs as amygdule-fillings, fracture coatings, thin quartz veins, breccia cements, and as replacements of primary minerals.

Locally, chloritization, argillization, and sericitization occur in a halo surrounding mineralized faults. Epidote locally occurs within this halo at depth and indicates temperatures of formation >200°C (Fig. 5.1). In the Center and Carlisle mines, altered zones occur between two subparallel veins. Near the surface, the altered zones consist of illite, kaolinite, chlorite, quartz, iron oxides, and lithic fragments. This assemblage grades with depth to predominantly illite and quartz zones within silicified andesite cut by stockwork veins of illite, quartz, and chlorite (Appendix 11.3; Maps 4, 5). This zone disappears with a dramatic decrease in metal concentrations in the footwall vein although metallic mineralization continues in the hanging wall vein (Map 4). Late primary calcite and hematite veins cut older alteration. Elsewhere in the district the halo consists of silicified and bleached rocks adjacent to the vein and grading into green rocks with chlorite and epidote away from the vein.

5.2.3 Regional post-mineralization alkali-chloride alteration

Superimposed on older alteration and mineralization is a regional post-mineralization alkali-chloride alteration. This late alteration is characterized by veinlets, typically less than a few millimeters wide, crosscutting older alteration and mineralization. These veinlets consist predominantly of quartz, chlorite, calcite, hematite, and locally zeolites (mordenite, thompsonite). Oxidation, supergene alteration, and weathering also occurred during this late alteration. Oxidation and remobilization of iron and manganese minerals have resulted in regional fracture coatings and staining by iron and manganese oxides. Some supergene alteration and oxidation are currently active at the Carlisle and Ontario mines where acidic waters are precipitating chalcanthite and other base-metal carbonates and oxides along the pit and adit walls.

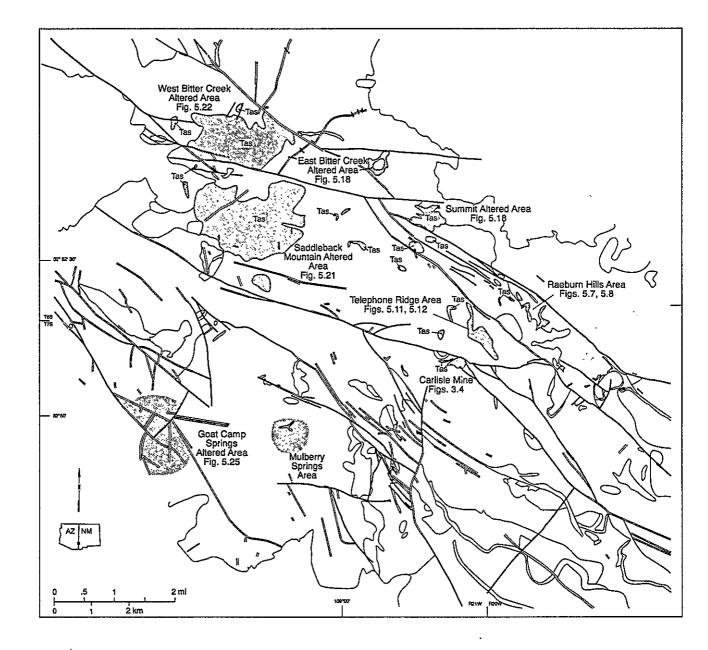

Figure 5.4 Areas of acid-sulfate alteration in the Steeple Rock mining district

5.3 Acid-sulfate alteration (advanced argillic)

5.3.1 Description

Several areas of intense acid-sulfate (advanded argillic) alteration superimposed on regional alkali-chloride alteration have been mapped in the district (Fig. 5.4; Maps 1, 2). Several of these areas are located near mineralized areas: Telephone Ridge north of the Carlisle and Center mines, a ridge east of the Summit mine, at the Bank mine, and at Goat Camp Springs. Other altered areas are in the vicinity of mineralized faults. Faults may occur in the altered areas; however, the alteration is typically too intense to accurately map them. Only a few faults are therefore mapped (Maps 1, 2). Original lithologies are typically observed and many areas are mapped as Tas on Maps 1 and 2; however, stratigraphic position and relict textures suggest that original lithologies were andesites and dacites (Summit Mountain and Dark Thunder Canyon formations), sedimentary rocks, and ash-flow tuffs.

The altered areas can be differentiated into three zones on the basis of mineralogy, texture, and inferred temperatures (Fig. 5:1) as (1) clay zone, (2) silicified zone, and (3) massive silica/chert zone. Boundaries between the zones are typically gradational and are characterized by quartz content and texture. Examination of drill core at the Carlisle, Center, and Summit mines indicates that two to three vertical zones of alteration occur separated by zones of alkali-chloride alteration.

The mineral assemblages are related to temperature similar to alkali-chloride alteration assemblages (Figure 5.1). Generally, the mineral assemblages suggest that the clay zone is typically the lowest temperature (<200°C), whereas the massive silica/chert zone is the highest temperature (>200°C). The mineralogy also confirms low pH fluids, as reflected by the phases present, specifically kaolinite, alunite, and pyrophyllite (White et al., 1988; Simmons et al., 1992; Mitchell and Leach, 1991).

5.3.2 Clay zone (Tasc)

The outermost altered zone in the acid-sulfate altered areas in the Steeple Rock district

is designated the clay zone, which is characterized by the alteration and replacement of the matrix and primary minerals in the host rock by kaolinite, illite, quartz, hematite, and locally illite/smectite, pyrite, anatase, tridymite, diaspore, alunite, despujolsite(?), and rare pyrophyllite. This mineral assemblage results in bleached and iron-stained rocks that occur in multiple shades of white, red, yellow, orange, purple, green, brown, and black. The intensity of alteration varies and locally some primary minerals such as quartz, titanite, zircon, and apatite are locally preserved (Appendix 11.2). Relict primary textures of original lithologies, such as trachytic and porphyritic, are also locally preserved. Some areas within the clay zone are soft and friable and consist only of clay minerals.

Commonly, the clay zone is also characterized by fine-grained, sugary, and vuggy texture, sometimes referred to as silica residue. Silica residue is formed in modern geothermal systems by leaching of the host rock by acid waters, which dissolve the alkali elements, leaving behind only silica, aluminum, iron, and titanium (P. R. L. Browne, unpubl. report, 1992). The porous residue allows additional fluids to pass through the rock which locally deposit secondary minerals in the void spaces.

5.3.3 Silicified zone (Tassi)

The silicified zone is typically the most extensive zone in most acid-sulfate altered areas in the district and is intermediate in composition and texture between the clay and massive silica/chert zones. This zone is characterized by alteration and replacement of primary minerals by quartz, kaolinite, illite, and locally pyrite, diaspore, pyrophyllite, alunite, jarosite, despujolsite(?), tridymite, anatase and other titanium oxides. The intensity of alteration varies, but is typically higher than in the clay zone and increases to 100% near the massive silica/chert zone (Appendix 11.2). Quartz content is typically high (>60%) and increases toward the massive silica/chert zone. Local areas of less intense altered rocks surrounded by intensely altered rocks are common. Relict primary textures are common.

These rocks are usually bleached and iron stained and occur in multiple shades of

white, red, yellow, orange, purple, green, brown, and black. Textures vary from fine- to medium-grained, massive to brecciated to vuggy to sugary. Silica residue, silica deposition and replacement are common. In some thin sections, thin quartz veins cut the altered rock. Quartz also locally replaces primary minerals such as feldspar, pyroxenes, and amphiboles.

Local areas of intense brecciation and hydrofracturing occur in this zone. Breccias of various lithologies with differing alteration types and intensities are cemented by silica (Fig. 5.5). These breccias are poorly sorted, randomly oriented, and consist of angular fragments. There are no chilled or altered zones surrounding the breccia fragments. Locally the breccias form a jigsaw pattern where the pieces could be put back together (hydrofracturing or hydrobrecciation). The rock fragments are rarely in contact with one another and they do not appear to have formed by grinding. Rock fragments are typically less than 1 m in diameter.

Hydrothermal explosions or eruptions are common in near-surface geothermal systems (Muffler et al., 1971; Phillips, 1972; Fournier et al., 1991; Sigvaldason, 1992). A hydrothermal explosion takes place when water flashes to steam and violently disrupts the confining rocks and expels water, steam, and solid material. A hydrothermal explosion or eruption is not a volcanic eruption because no magma is directly involved. One result of these explosions are geysers. Craters formed by hydrothermal explosions can range in size from very small (2–50 m) to as large as 1500 m or more (Muffler et al., 1971). The local areas of brecciation and hydrofracturing in the Steeple Rock district may have formed by hydrothermal explosions or eruptions and represent either the surface or subsurface remnants of these violent events. Some areas of acid-sulfate alteration in the Steeple Rock district have circular, elongate, or horseshoe shapes, which along with the texture, composition and appearance are suggestive of hydrothermal eruptions (i.e. east of the Summit vein; Fig. 5.19; Sigvaldason, 1992).

5.3.4 Massive silica/chert zone (Tass)

5.

The innermost, central zone of the acid-sulfate alteration is designated the massive

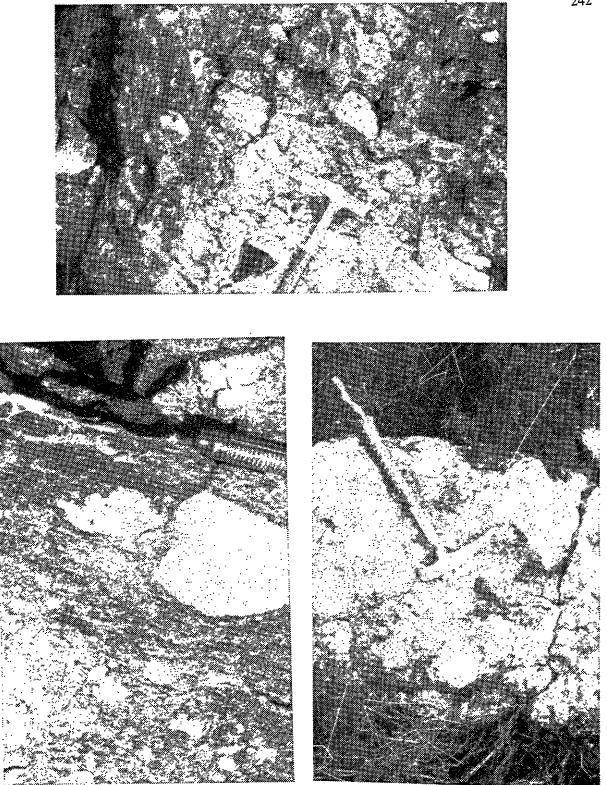

Figure 5.5—Hydrothermal breccias from the Raeburn Hills area.

silica/chert zone. This zone is referred to by Biggerstaff (1974) as quartz knobs, jasperoids, and silica replacement caps; and is characterized by >90% silica, typically as quartz and/or chert with minor amounts of kaolinite, anatase, alunite, pyrophyllite, hematite, and pyrite (Appendix 11.3). These rocks are typically white to light gray in color and extremely hard. The massive silica/chert zone has a fine- to medium-grained, massive to brecciated to locally vuggy texture. Intensity of alteration is typically 100% and relict textures are seldom preserved (Appendix 11.2). Locally areas of brecciation and hydrofracturing occur, similar to areas in the silicified zone. This zone formed by dissolution of most elements by the acid fluids and subsequent recrystallization and/or deposition by silica.

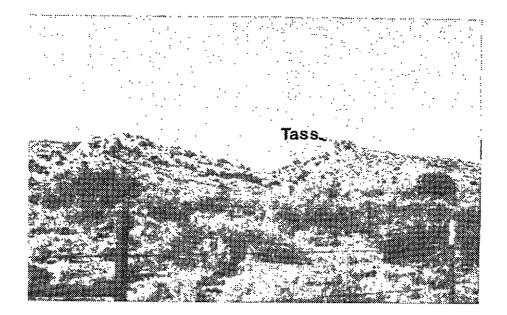

5.4 Description of areas

5.4.1 Raeburn Hills area

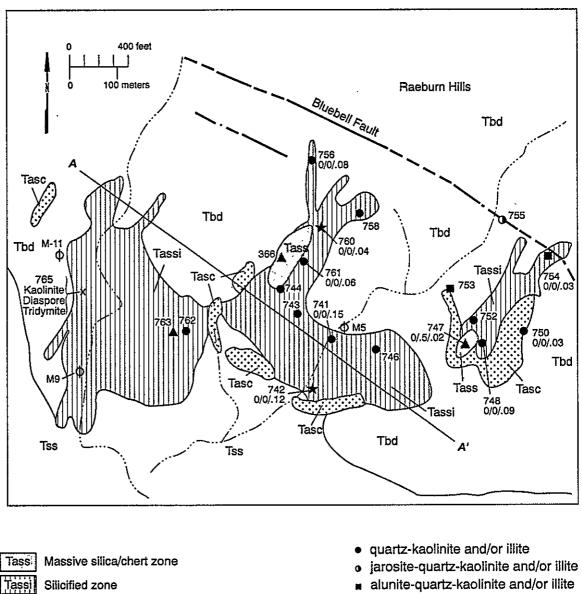

Raeburn Hills is located along the Bluebell fault in the east-central part of the district (Fig. 5.4, Maps 1, 2). The area is named after a windmill in the arroyo that cuts the alteration. FMC drilled 12 holes (reverse circulation) in the area, but only limited data were available for this study.

The altered rocks in the Raeburn Hills area were originally andesites of the Dark Thunder Canyon formation, an ash-flow tuff of unknown age, and volcaniclastic sedimentary rocks of the Summit Mountain formation. Intensity of alteration varies. All three advanced argillic alteration zones are present in the area (Figs. 5.6, 5.7, 5.8). There are three areas of massive silica/chert zones: two capping hills (Fig. 5.8) and a third forming the knob in the northern part of the area (Fig. 5.9). The acid-sulfate altered rocks overlie alkali-chloride altered andesites and sandstones. The total thickness of acid-sulfate alteration is probably less than 200 m based on surface exposure and limited drill data (Fig. 5.8).

Quartz, kaolinite, and iron and manganese oxides are common to all three zones. Locally, tridymite, diaspore, alunite, and illite occur in the clay zone and alunite, pyrophyllite, and illite occur in the silicified zone (Fig. 5.7; Appendix 11.3). Barite, calcite,

and pyrite are locally present in the silicified and massive silica/chert zones. Relict porphyritic textures characteristic of the porphyritic andesite, sandstone, and tuff are locally preserved. Pyrite casts are common in the silicified zone. Hydrothermal brecciation and hydrofracturing are preserved in the silicified and massive silica/chert zone (Fig. 5.5).

A geochemical sampling program by FMC indicates that samples from this area are relatively low in gold, silver, and mercury, although local anomalies do occur (Table 5.2). A map showing location of FMC samples was not available; however, samples for this study confirm the low values (Fig. 5.7; Appendix 11.5). One sample contained 0.5 oz/ton (17.1 ppm) Ag (#747, Appendix 11.5).

Table 5.2—Summary of geochemical analyses of Raeburn Hills altered area reported by FMC (both surface and drill cuttings samples; E. M. Crist, pers. comm. October 1988) and reported in this study (Appendix 11.5). Average crustal abundances and in basalts from Krauskopf (1979).

Cu	<200	6-41	50	100
Pb	<200	4.8-63	12.5	3.5
Zn	<200	4.8-27	70	100

Epithermal veins along the Blue Bell fault cut and are younger than the acid-sulfate alteration (Fig. 5.7). Silicification and minor clay alteration occurs along the veins. Elsewhere, veins cut alkali-chloride altered andesites with only weak silicification. Locally jarosite is present in the wallrock.

5.4.2 Telephone Ridge area

Telephone Ridge lies north of the Carlisle and Center mines and west of Raeburn Hills (Fig. 5.4; Maps 1, 2). It is bounded on the south by the Carlisle fault and on the east by the East Camp fault. Pioneer Nuclear drilled four diamond drill holes; logs and chemical analyses are summarized in Appendix 11.1. The core has disappeared.

The rocks on Telephone Ridge are intensely altered and the original lithology is locally difficult to determine. Hedlund (1990a) mapped them as rhyolite intrusives. Biggerstaff (1974), Powers (1976), and Wahl (1980) mapped them as rhyolite ash-flow tuff. Drill data do not support an intrusive rhyolite; however, it is possible that an intrusive was missed by the large spacing of the drill holes. Hydrothermal breccias are common along the ridge and are similar in appearance to autobreccias observed in rhyolite plugs and domes. However, the breccias also could be attributed to hydrothermal eruptions. Outcrop examinations and petrographic studies suggest that the original rocks were ash-flow tuffs, sandstones, and hydrothermal breccias (Appendix 11.2). This area is mapped as altered tuff, sediments, and andesites undifferentiated (Tas) because of the intense alteration (Maps 1, 2).

All three alteration zones are present in the area (Figs. 5.10, 5.11, 5.12). The most impressive outcrops are the massive silica/chert zone (Figs. 5.10, 5.13), which forms some of the largest and best exposures of this zone in the district. Silicified and clay zones surround the massive silica/chert zone and together overlie slightly altered andesite flows and tuffs (Fig. 5.14). Some areas of alkali-chloride altered rocks are surrounded by acid-sulfate altered rocks. Some fractures within the alkali-chloride altered rocks are bleached and the alkali-chloride altered andesites are sandwiched between acid-sulfate altered rocks suggesting that permeability and lithology controlled fluid migration (Fig. 5.16, 5.17) and indicate migration of gases. Fossil fumaroles (or vesicle cylinders) may also indicate gases escaping during deuteric cooling of the flows. However, they are only found at Telephone Ridge beneath zones of acid-sulfate alteration and suggest a spatial relationship to the alteration.

Figure 5.10—Massive silica/chert zone at Telephone Ridge overlying silicified zone. Looking north.

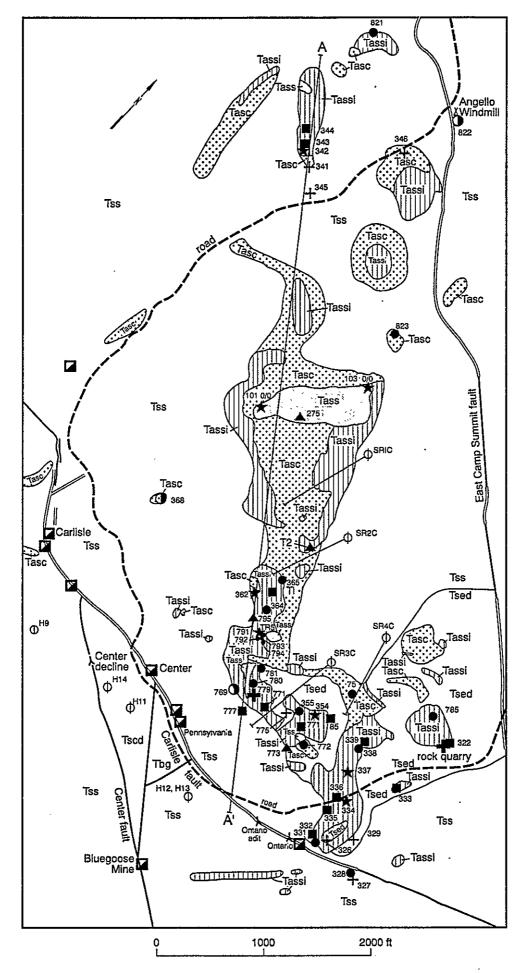

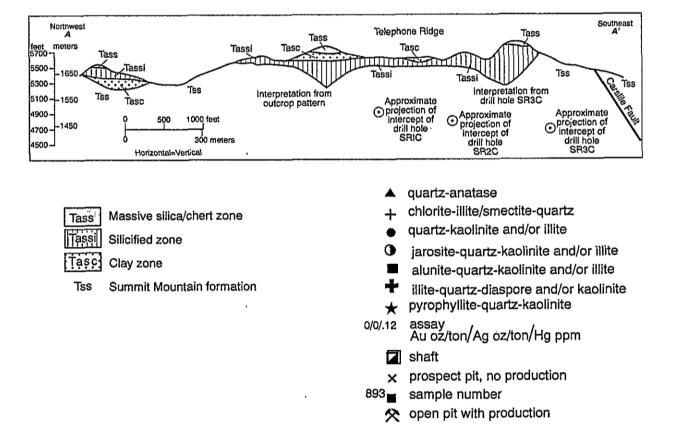

Figure 5.11. Geologic and alteration map of Telephone Ridge. Legend on next page

Figure 5.13-Closeup view of massive silica/chert zone at Telephone Ridge.

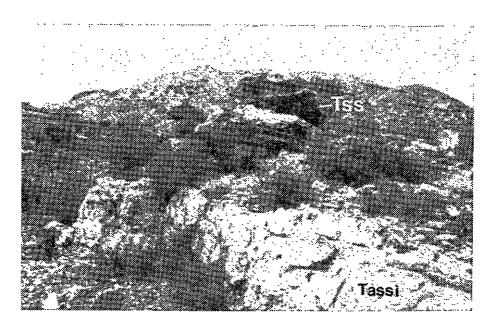

Figure 5.14—Silicified zone overlain by slightly altered andesite lava.

A variety of textures is preserved in outcrop and thin sections. Original phenocrysts are completely or nearly completely replaced by alunite, pyrophyllite, quartz, iron oxides, and kaolinite. Late post-mineralization alkali-chloride alteration is superimposed locally over acidsulfate alteration; quartz-adularia veinlets cut acid-sulfate alteration locally. Quartz-pyrite veins are common. Ghosts of plagioclase phenocrysts similar to those found in porphyritic andesites are locally preserved. Liesegang-banded altered rocks are common.

The acid-sulfate alteration extends from Telephone Ridge southward to the hanging wall of the Carlisle fault at the Ontario mine (Fig. 5.11). The footwall of the Carlisle fault at the Ontario mine exhibits silicification and chloritization (i.e. alkali-chloride alteration). Acid-sulfate alteration is present at the Carlisle mine forming a partial cap to epithermal mineralization (Fig. 3.4), however, some veins do penetrate the acid-sulfate alteration and cut the earlier altered rock (Fig. 5.11). There is no acid-sulfate alteration at the Center or Pennsylvania mines. If present, acid-sulfate altered rocks could have been eroded away.

The mineralogy of samples from Telephone Ridge and near the Ontario mine is shown in Figure 5.11. Figure 3.4 illustrates the mineralogy at the Carlisle mine. In addition, fluorite, barite, calcite, and pyrite are locally disseminated throughout the altered rock in trace amounts. Quartz, kaolinite, and iron oxides are abundant.

Anomalously high gold, silver, and mercury concentrations are locally present at Telephone Ridge and are typically associated with the silicified and massive silica/chert zones (Fig. 5.11; Appendix 11.5). Surface sampling by Pioneer Nuclear Corp. indicates anomalous concentrations of gold (>0.02 ppm), silver (>0.2 ppm), mercury (>0.10 ppm), and arsenic (>30 ppm) occur in the vicinity of the massive silica/chert zone (Pioneer Nuclear, geochemical map).

A series of samples was collected vertically along a steep hillside west of Telephone Ridge (#341-346; Appendix 11.4, 11.5; Figs. 5.15, 5.18). The intensity and rank (temperature) of alteration increases from bottom to top, as indicated by the mineral assemblage. Mineralogy also changes (from bottom to top): illite/smectite to illite-kaolinite

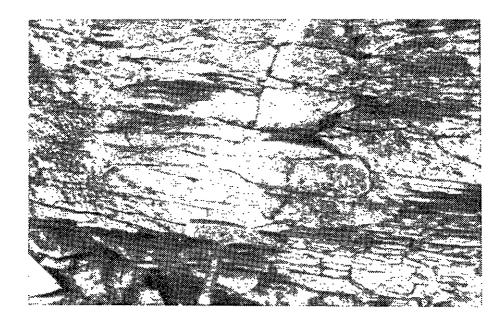

Figure 5.15—Bleached clay zone along fracture in slightly altered andesite lava. The lava is overlain by the silicified zone.

. *•*

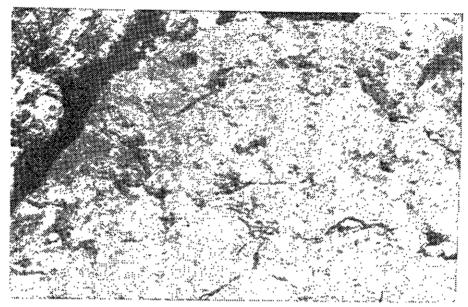

Figure 5.16—Fossil fumaroles in andesite lava at Telephone Ridge, underlying the massive silica/chert zone (Fig. 5.10). Circular features in the andesite are the top of fumaroles.

(clay zone) to kaolinite to pyrophyllite-diaspore-kaolinite (silicified zone) to alunite-kaolinite with local anatase and pyrophyllite (silicified zone). A discontinuous silica replacement body (massive silica/chert zone) occurs on top. Subsurface and surface data indicate that acid-sulfate altered rocks are probably less than 400 m thick and overlie alkali-chloride altered rocks (Appendix 11.1).

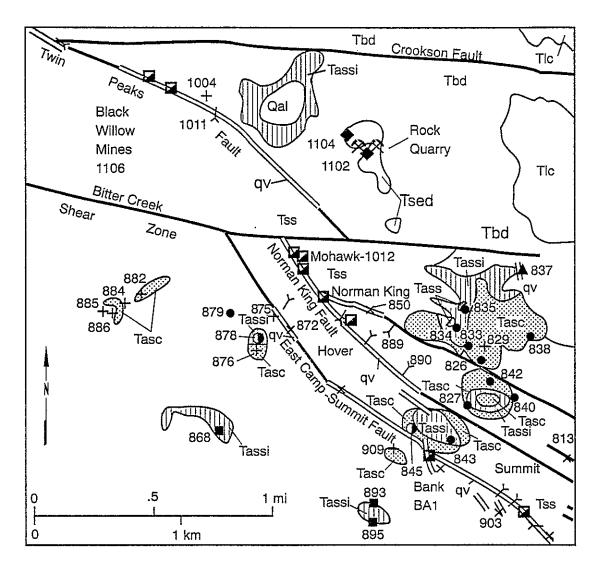

Examination of drill core along the Carlisle fault indicates that similar acid-sulfate zones are sandwiched between alkali-chloride altered rocks. Several acid-sulfate zones exist in the subsurface but none are extensive (Appendix 11.1).

5.4.3 Summit and East Bitter Creek altered zones

Acid-sulfate alteration occurs along some of the ridges west of the Summit mine and elsewhere along the East Camp-Summit and Twin Peaks faults (Fig. 5.10). Biron Bay Resources Inc. has drilled numerous diamond drill holes along the East Camp-Summit fault, some of which have penetrated the acid-sulfate alteration (Appendix 11.1).

The altered rocks were originally andesites and, perhaps, tuffs of the Summit Mountain formation. Intensity of alteration varies. All three zones of acid-sulfate alteration are locally present (Fig. 5.19). The massive silica/chert zone is rare, outcrops are typically small and form the caps of the ridges, and it is surrounded by the silicified and clay zones. Synmineralization alteration may be superimposed on acid-sulfate alteration at the Bank mine where the area is completely altered to clay and quartz. Total thickness of the acid-sulfate alteration is probably less than 200 m.

The mineralogy of samples collected is shown in Figure 5.18. Illite is predominant in the silicified and clay zones; kaolinite occurs in lesser amounts. Calcite, gypsum, pyrite, tridymite, and barite are locally common in trace amounts in the silicified and clay zones. Liesegang-banded altered rocks are common (Fig. 5.20). Hydrothermal brecciation and hydrofracturing are common in the silicified and massive silica/chert zones. Several areas have circular, elongate, or horseshoe-shaped outcrops that are perhaps indicative of

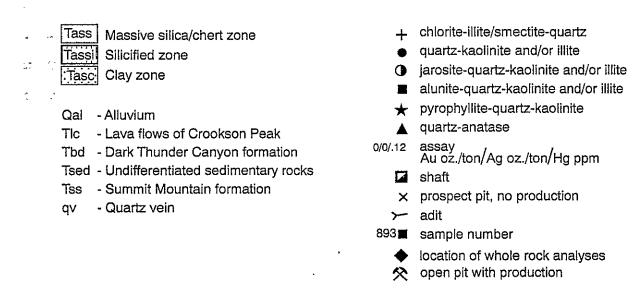

Figure 5.19 Geology and alteration of the Summit and East Bitter Creek altered areas

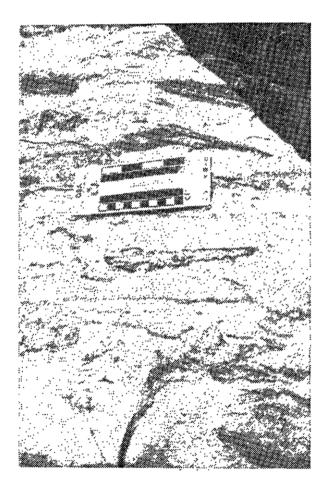

Figure 5.20-View of liesegang-banded altered rock.

hydrothermal vents or craters (Fig. 5.19). Several vertical zones are present in outcrop and in the drill core (Appendix 11.1).

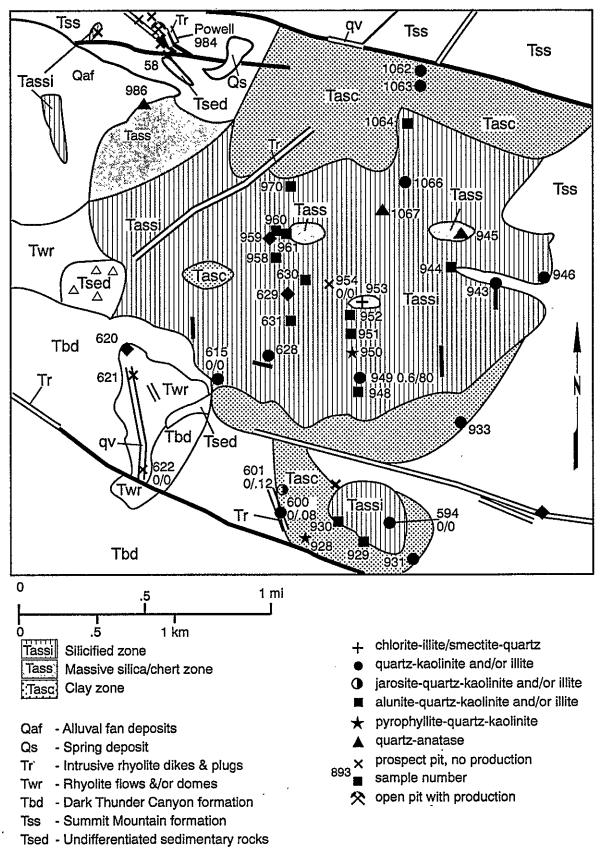

5.4.4 Saddleback Mountain and West Bitter Creek areas

The largest and most extensively acid-sulfate altered areas are the Saddleback Mountain and West Bitter Creek areas (Fig. 5.10). The Bitter Creek fault zone separates the two areas and the West Bitter Creek area is bounded on the north by the Twin Peaks fault (Figs. 5.21, 5.22).

Saddleback Mountain is one of the most rugged and highest mountains in the mapped area and most of the mountain is altered (Figs. 5.23, 5.24). All three zones are present in both areas; the massive silica/chert zone caps the uppermost ridges. The silicified zone surrounds the massive silica/chert zone and is the most extensive zone at Saddleback Mountain. The clay zone forms the lower foothills and is more extensive at West Bitter Creek. Alteration is at least 500 m thick in places (Map 3).

The mineralogy is illustrated in Figures 5.21 and 5.22. Kaolinite, illite, and quartz with local pyrophyllite, pyrite, and jarosite occur in the clay zone. Quartz, kaolinite, illite, alunite, jarosite, pyrite, barite, and anatase occur in the silicified zone. The massive silica/chert zone consists of quartz, anatase, pyrite, and alunite (Appendix 11.3). Large veins (up to 1 m wide) of gray to gray-white alunite-quartz (\pm pyrite) and green-gray to gray kaolinite-quartz cut the silicified zone locally. Areas of alkali-chloride altered andesites are preserved throughout and are surrounded by acid-sulfate altered rocks. A rhyolite dike striking northeast cuts the acid-sulfate altered rocks. Vertical pipes of quartz-alunite are preserved in Wampoo Canyon and are capped by alkali-chloride altered andesites (Wahl, 1980).

The original rocks were probably andesites and volcaniclastic sediments of the Summit Mountain formation, although one or two rhyolite ash-flow tuffs may also be present. The intensity of alteration is high and much of the area was mapped as altered rocks

Stratigraphic symbols are defined in figure 2.2.

Figure 5.21 Geologic alteration map of Saddleback Mountain area

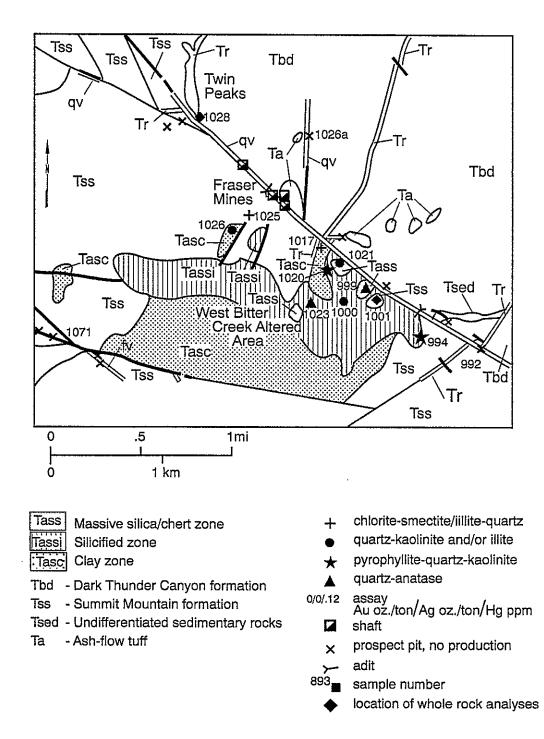

Figure 5.22 Geology and alteration map of the West Bitter Creek area

Figure 5.23-Aerial view of Saddleback Mountain, looking north.

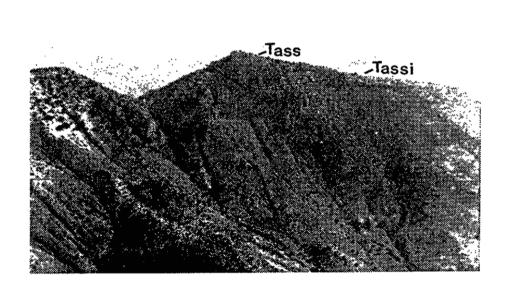

Figure 5.24-Closeup aerial view of massive silica/chert zone at Saddleback Mountain, looking north.

undifferentiated (Tas; Maps 1, 2). One age determination of quartz-alunite altered rock from Saddleback Mountain is reported as 31.3 Ma (Table 2.1; Hedlund, 1993), which is the reported age of the Summit Mountain formation (Table 2.1). Sulfur isotope data are also reported by Field (1966), which will be discussed in section 6.1.2.

5.4.5 Goat Camp Springs area

The Goat Camp Springs area lies west of Vanderbilt Peak (Fig. 5.10) in the vicinity of the Goat Camp Springs fluorite mines (Ontario, Stotts, Dean, Luckie mines; Maps 1, 2). Several mineralized faults and rhyolite/rhyodacite dikes cut the acid-sulfate alteration (Fig. 5.25). Some dikes have been silicified and sericitized, probably in response to quartz and fluorite mineralization, but the intrusives have not been affected by acid-sulfate alteration.

Intensity of alteration varies. Outcrops in this area are colorful, forming bleached and variegated, barren wasteland (Fig. 5.26), similar in appearance and composition to the hot springs, mud pots, and geysers at Norris Geyser Basin, Yellowstone National Park (Fig. 5.27). Hydrothermal breccias with iron and manganese oxides occur along some ridges forming a silicified zone (Fig. 5.25). The massive silica/chert zone is not exposed in this area. The clay zone is the most extensive zone. Some isolated patches of acid-sulfate altered rock are surrounded by alkali-chloride altered rock. Large areas of illite with little quartz occur in the clay zone. Kaolinite is locally present.

Mineralogy of samples from this area is shown in Figure 5.25. Barite, calcite, pyrite, and tridymite are locally present, especially in the hydrothermal breccias. Sampling for this study detected no gold or silver anomalies (Appendix 11.5); however, sampling by R. S. Powers (unpubl. report, 1968) indicates some local areas may contain anomalously high gold and silver (Table 5.3).

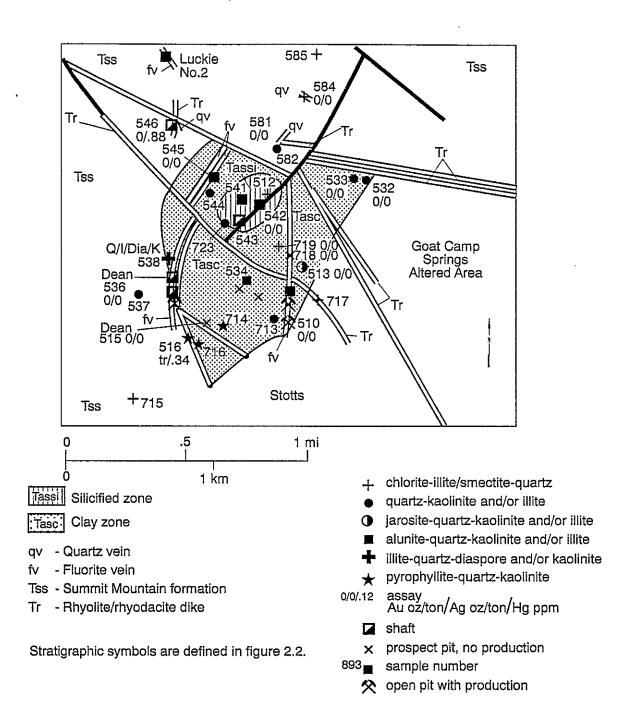

5.4.6 Mulberry Springs area

The Mulberry Springs area lies west of Vanderbilt Peak (Fig. 5.10). This area is less

Table 5.3—Summary of geochemical analyses of altered samples from the Goat Camp Springs area from R. S. Powers (written communication, 1968) and this study (Appendix 11.5). Total number of samples: Powers had 104 samples for Au, Ag, and Hg and 4 samples for Cu, Pb, Zn, and Mo. There were seven samples from this study. Average crustal abundances and average basalt from Krauskopf (1979).

intensely altered and only the clay zone is exposed. Andesite and volcaniclastic sediments of the Summit Mountain formation have been altered to kaolinite and quartz. Iron oxide staining and fracture coatings are common. Original textures are preserved locally. Outcrops are rare (Map 1). No samples were collected in this area during the present study.

5.5 Mineralogy

In this section, the distribution, textures, and description of the major alteration minerals, both alkali-chloride and acid-sulfate, are presented. Techniques used include literature search, field observations, petrography, XRD, and chemical analyses.

5.5.1 Quartz, SiO₂

The predominant alteration mineral in the Steeple Rock district is quartz. Quartz is common to all types of alkali-chloride and acid-sulfate alteration. Quartz occurs as (1) replacement of primary minerals, especially feldspar; (2) vug and other open-space fillings; (3) breccia cement; and (4) veinlets. The massive silica/chert zone (acid-sulfate alteration) consists of >90% quartz. Some quartz may have originally been deposited as amorphous silica or other silica minerals (tridymite, cristobalite, chalcedony, chert) and subsequently converted to quartz. This quartz typically exhibits undulatory or wavy extinction in thin section (Sander and Black, 1988). Quartz is typically white to colorless to tan or gray. It generally occurs as clear, subeuhedral crystals to extremely fine-grained massive replacements. Rare euhedral, double terminated crystals occur in vugs. Amethyst quartz is present in epithermal veins and as vug-fillings near the epithermal veins.

5.5.2 Pyrite, FeS₂

Pyrite is an abundant alteration mineral in the district, including drill core samples. It

ranges in abundance from trace to 40% and is found in all types of alteration. Grain size varies from submicron to several millimeters. It typically occurs as euhedral to subhedral cubic crystals or aggregates that are disseminated throughout the host rock. Some pyrite replaces primary magnetite, ilmenite, pyroxenes, and amphiboles. It is easily altered to iron oxides in the near-surface environment.

5.5.3 Chlorite, $Mg_3(Si_4O_{10})(OH)_2 \cdot Mg_8(OH)_6$

Chlorite is restricted to alkali-chloride altered rocks; it is unstable and converts to other minerals or is dissolved by acidic waters in the acid-sulfate environment. Specific chlorite minerals have not been identified yet. Chlorite occurs as (1) replacement of original matrix, (2) replacement of iron and magnesium silicates, and (3) as thin veins and veinlets (Fig. 5.3). It results in a greenish-colored rock. In thin section, it occurs as minute crystals, aggregates, and foliated masses.

5.5.4 Adularia, KAlSi₃O₈

Adularia is a low-temperature variety of K-feldspar and is restricted to the alkalichloride alteration. Locally, quartz-adularia veinlets cut the acid-sulfate alteration, but adularia is not stable under acidic conditions (Fig. 6.9). Adularia found in this environment represents superimposed, younger alkali-chloride alteration. Adularia occurs as small replacements of primary feldspar and vug fillings ($<0.05\mu$ in size). Adularia content rarely exceeds 1% in any altered rock. It is similar in appearance to quartz except adularia exhibits cleavage.

5.5.5 Clays

Clay mineralogy is important in determining the rank of alteration; many clays are

indicative of temperature (Fig. 5.1). Clays are common in all types of alteration in the district.

In the alkali-chloride altered rocks, the predominant clay mineral groups present are smectite, illite/smectite, illite, and less common kaolinite. Chlorite is abundant and has been previously described. Illitic clays are common in syn-mineralized altered zones and probably represent higher temperatures (Fig. 5.1). Smectite and illite/smectite are rare to absent immediately adjacent to and within veins. Pure smectite clays or predominantly smectite/illite clays are less abundant but are found locally away from veins. Chlorite/smectite clays are also abundant in some areas and locally form a halo surrounding vein deposits. Locally, kaolinite and kaolinite-illite form gray to green veins and veinlets in altered areas near the veins (3-4 cm).

In the acid-sulfate altered rocks, smectitic clays are absent except around the margins of such alteration. Kaolinite and illite are the predominant clay mineral groups in the acid-sulfate altered rocks and are indicative of deposition by low pH fluids. Clays are abundant in this zone and decrease in abundance toward the massive silica/chert zone. Kaolinite is typically finely disseminated throughout the rock, filling void spaces and replacing primary minerals. Kaolinite is typically white to green to gray and when intergrown with quartz becomes rather hard and difficult to identify except by XRD. XRD analyses of randomly packed powders indicated kaolinite and dickite are present locally. Some veins are several centimeters wide. Illite is also green to gray to white, and finely disseminated throughout the rock, but locally occurs as very small tabular, moderate to high birefringence crystals. Illite typically indicates temperatures of formation greater than 200°C, whereas mixed layered clays indicate lower temperatures (<200°C; Fig. 5.1). Veins of white to green illite and quartz are locally common.

μ.

27

. 1.4 ٠,

5.5.6 Titanite (sphene), CaTiSiO₅

Titanite is common in both types of alteration in the district and is also a primary mineral in the volcanic rocks. It occurs as small anhedral crystals with high relief and high birefringence. It is semiopaque to opaque and is white in reflected light. Typically the crystals are absorbed or skeletal creating a spongy appearance. It is commonly identified only by XRD (Appendix 11.3).

5.5.7 Anatase/rutile/leucoxene, TiO₂

Anatase, rutile, and leucoxene are common alteration minerals in the district, especially in acid-sulfate altered rocks. These minerals may be complexly intergrown and occur as opaque, yellow to red to brown in thin section and white under reflected light microscopy. The crystals or aggregates are small (<0.05 μ m) and are identified by XRD (Appendix 11.3).

5.5.8 Epidote, Ca-Mg-Mn (Al,Fe)₃(OH)(SiO₄)₃

Epidote is found locally in the district and is restricted to alkali-chloride altered rocks. It occurs as replacement of primary and alteration minerals, veinlets, aggregates with chlorite, and as distinct fibrous aggregates. It is typically colorless to green in thin section, pleochroic, and has moderate birefringence. Epidote is an important alteration mineral because it indicates deposition from fluids at > 200°C (Fig. 5.1; Reyes, 1990; Simmons et al., 1992).

5.5.9 Carbonates

Various carbonate minerals occur in the altered rocks; for example calcite, dolomite, anhydrite, and siderite. They typically occur as replacements of primary minerals, vug

fillings, and veinlets; locally they form small rhombhedron-shaped crystals. They are especially common in alkali-chloride altered rocks and rare in acid-sulfate altered rocks. Bladed calcite indicates boiling (White and Hedenquist, 1990). Dolomite is typically deposited by fluids at $< 180^{\circ}$ C and anhydrite is typically deposited by fluids at $> 150^{\circ}$ C (Fig. 5.1).

5.5.10 Zeolites

Zeolites are present in low-temperature alkali-chloride altered rocks. Mordenite $(Ca, Na_2, K_2)Al_2Si_{10}O_{24} \cdot 7H_2O$ and gismondine $CaAl_2Si_2O_8 \cdot 4H_2O$ are more common in the andesites, but thompsonite $NaCa_2Al_5Si_5O_{20} \cdot 6H_2O$ and other low-temperature zeolites are also found. They typically occur as vug or open-space fillings and replacement of groundmass. They are indicative of temperatures <200°C (Fig. 5.1). Wairakite $CaAl_2Si_4O_{12}$ $\cdot 2H_2O$ is a higher temperature zeolite (220–300°C; Reyes, 1990) and is found in one sample (#178, Appendix 11.3)

5.5.11 Alunite, $KAl_3(OH)_6(SO_4)_2$

Alunite is found in the acid-sulfate altered rocks; typically in all three zones in varying amounts. Alunite is difficult to identify visually in the district. Its identification is confirmed only by XRD and petrographic studies, because it is fine-grained (<0.05 mm) and disseminated. Alunite is one end member of a series of sulfates that occur in several geologic environments, all of which are low pH environments. Alunite-group minerals are common products of hydrothermal alteration (specifically acid-sulfate alteration) and weathering and are found in modern hot springs, sedimentary rocks, and low-grade metamorphic rocks (Stoffregen and Cygan, 1990). In the Steeple Rock district, alunite locally occurs with pyrite, which, along with additional data, suggests a hydrothermal origin. Minerals of the alunite-group have the general composition $AB_3(SO_4)_2(OH)_6$ where A is typically K⁺, Na⁺, Pb⁺⁺, NH₄⁺, or Ag⁺ and B is typically Al⁺³ or Fe⁺³ (Brophy et al., 1962). The alunite-group consists of many mineral species, and nine of the more common minerals are (Brophy et al., 1962; Altaner et al., 1988):

Alunite – $KAI_3(SO_4)_2(OH)_6$ Natroalunite – $NaAI_3(SO_4)_2(OH)_6$ Ammonioalunite – $NH_4AI_3(SO_4)_2(OH)_6$ Jarosite – $KFe_3(SO_4)_2(OH)_6$ Natrojarosite – $NaFe_3(SO_4)_2(OH)_6$ Ammoniojarosite – $NH_4Fe_3(SO_4)_2(OH)_6$ Argentojarosite – $AgFe_3(SO_4)_2(OH)_6$ Beaverite – $Pb(Cu, Fe, AI)_3(SO_4)_2(OH)_6$ Plumbojarosite – $PbFe_6(SO_4)_2(OH)_6$

Solid-solution between the minerals is common (Brophy et al., 1962; Stoffregen and Cygan, 1990) but not well understood (Rye et al., 1992). Considerable solid-solution occurs between K⁺ and Na⁺ of the alunite (Al⁺³) and jarosite (Fe⁺³) series (Altaner et al., 1988; Stoffregen and Cygan, 1990), but solid-solution between the Al⁺³ and Fe⁺³ series appears to be minor in natural systems. In addition, PO_4^{-3} can substitute for SO_4^{-2} forming a series of aluminum phosphate minerals (Stoffregen and Alpers, 1987).

Only XRD and petrographic studies have been performed on the alunites from Steeple Rock; therefore the specific mineralogy is not well known. Chemical analyses and XRD patterns indicate that alunite, jarosite, natrojarosite, and natroalunite are present, but some of the other minerals may exist as well.

Alunite typically occurs as fillings of void spaces, thin veinlets (Fig. 5.28), and

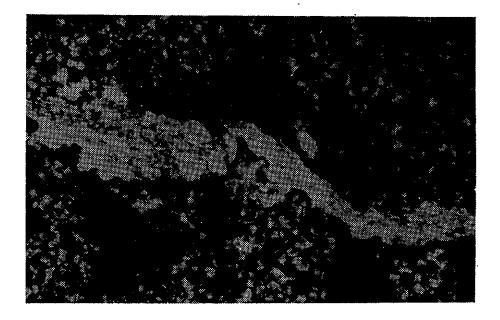

Figure 5.28—Photomicrograph of veinlet of alunite and quartz in silicified tuff.

.....

×.

replacement of primary minerals. It is generally intergrown with kaolinite and quartz. Identification of alunite is important because it indicates a low pH environment and alunite can be used in age determinations and isotopic studies.

5.5.12 Pyrophyllite, Al₂(Si₄O₁₀)(OH)₂

Pyrophyllite occurs only in the silicified and massive silica/chert zones of the acidsulfate alteration in the Steeple Rock district. It is fine-grained and occurs as disseminations, void-fillings, replacements of primary minerals, and as thin veinlets with quartz. In thin section, it commonly forms foliated and/or radiating lamellar aggregates (Fig. 5.29). Its identification in the district is primarily by XRD and petrographic studies. Pyrophyllite is an important mineral because it indicates desposition by acidic fluids >200°C (Fig. 5.1).

5.5.13 Diaspore, HAlO₂

Diaspore is found in acid-sulfate altered rocks. It typically occurs as veins, some as wide as several centimeters, although locally it is disseminated throughout the altered rock. It is typically white to green to yellow to brown to colorless, transparent to translucent, and occurs with quartz, alunite, kaolinite, and iron oxides.

5.5.14 Despujolsite, Ca₃Mn(SO₄)₂(OH)₆ · 3H₂O (?)

Despujolsite is tentatively identified by XRD (Appendix 11.3) and occurs in the acidsulfate altered areas, specifically the clay and silicified zones. It is yellow to brown, finegrained, and intergrown with iron oxides. Whole-rock chemical analyses are consistent with the occurrence of this mineral. However, this is a less common mineral found in vein deposits (Fleischer, 1969) and microprobe and SEM studies are required before this mineral is confirmed.

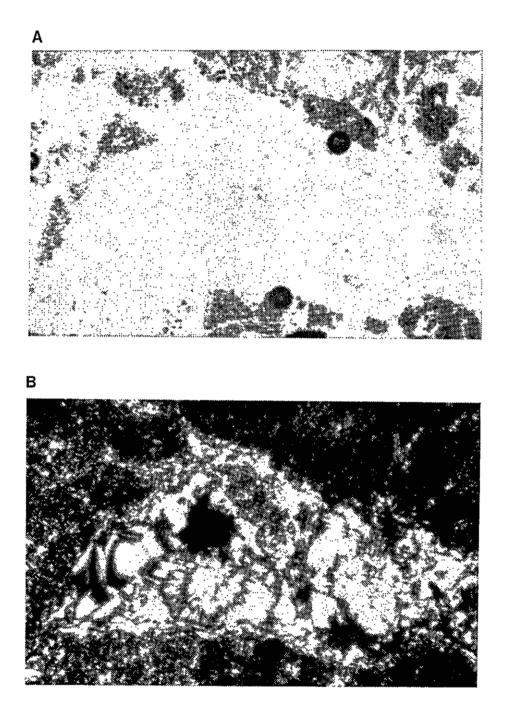

Figure 5.29—Photomicrograph of pyrophyllite filling vesicle in silicified andesite. a) plane light, b) crossed nicols. Field of view is approximately 0.5 mm.

5.6 Chemistry of alteration

Numerous surface and drill core samples of altered rocks from the Steeple Rock district were sampled and analyzed for major and trace elements (Appendix 11.4). The chemical variations produced by alteration reflect changes in the mineral assemblage which together are influenced by temperature and pressure, composition of the parent rock, composition of the altering fluids, permeability and duration of the alteration process (section 5.1).

The most extensive alteration in the district is by alkali-chloride waters and these altered rocks are characterized by differences in geochemistry (section 2.4). The mafic rocks are locally extensively altered to quartz, chlorite, pyrite, and other secondary minerals and exhibit a corresponding increase in silica, magnesium, and locally iron, relative to unaltered mafic rocks (Appendix 11.4c). The silicic rocks (rhyolites, ash-flow tuffs) exhibit variable changes in concentrations of silica and the alkali elements as a result of the alteration of feldspar and groundmass to quartz and clay minerals (kaolinite, illite, smectite, chlorite).

A vertical section through multiple flows of andesite of the Summit Mountain formation in USBM drill hole H9 was sampled and analyzed for major and trace elements (Appendix 11.4c, Figs. 5.30, 5.31). Although there is some scatter in the data, the andesites increase in K_2O , Ba, Rb, Sr and Zn concentrations and decrease in Al_2O_3 and Y concentrations toward the vein.

The acid-sulfate altered rocks exhibit more dramatic changes in the chemical composition as a result of dissolution by acid fluids and subsequent deposition of quartz, kaolinite, illite, alunite, and other secondary minerals. Differences in chemical composition between acid-sulfate and alkali-chloride altered rocks can be observed in the USBM drill hole H-10. The acid-sulfate altered rocks have higher concentrations of SiO₂ and Sr and lower concentrations of MgO, CaO, K₂O, Zn, and Rb relative to the alkali-chloride altered rocks (Figs. 5.32, 5.33). Elsewhere in the Steeple Rock district, many samples of acid-sulfate altered rocks within the

ALKALI-CHLORIDE ALTERED ROCKS

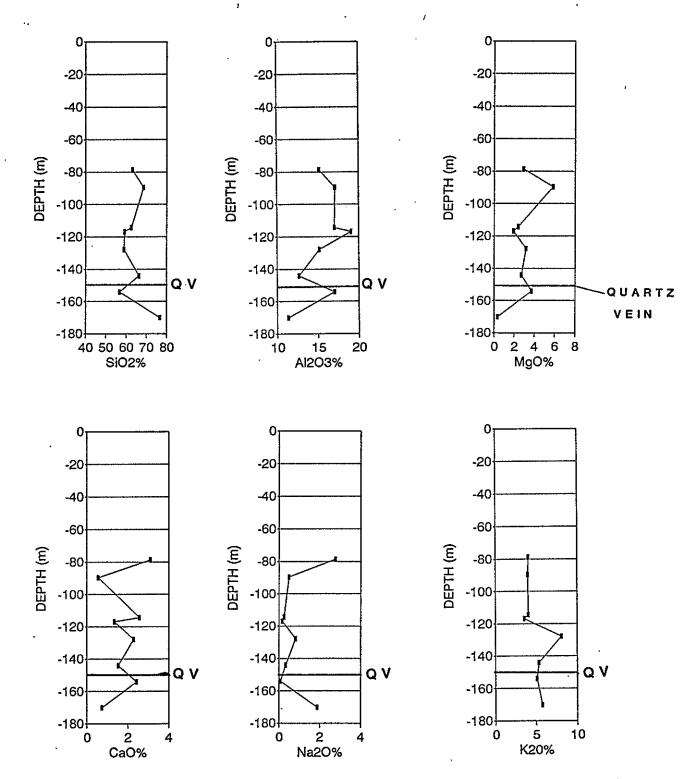

Figure 5.30—Concentrations of selected major elements with depth in USBM drill hole H9. H9 is located between the Carlisle and Center mines (Map 5) and consists of andesites, Summit Mountain formation. Quartz vein is at a depth of 151-153 m.

ALKALI-CHLORIDE ALTERED ROCKS

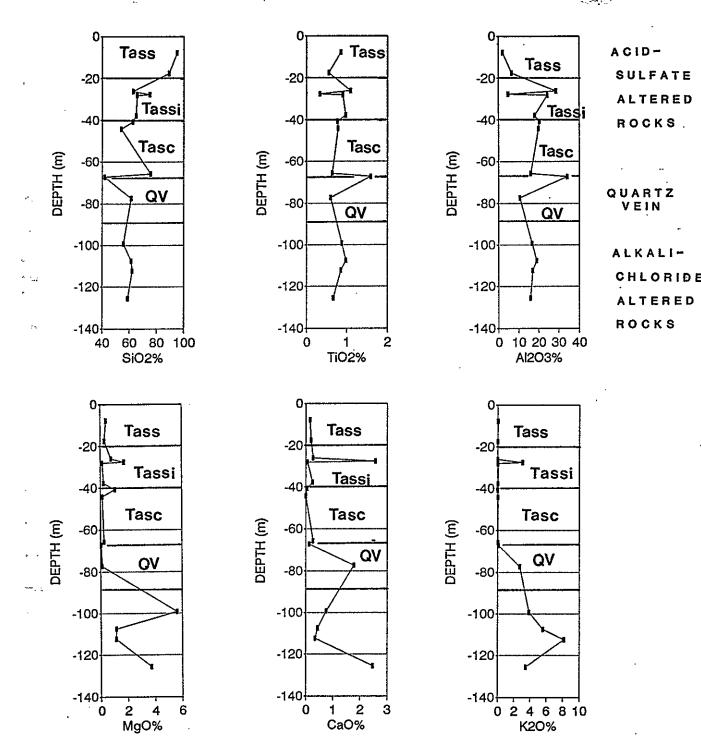

Figure 5.32—Alteration zonation and concentrations of selected major elements with depth in USBM drill hole H10. H10 is located at the Carlisle mine (Fig. 3.4, Map 5). The upper 67.1 m are in altered rocks (Tas) and the lower rocks are in andesites of Summit Mountain formation (Appendix 11.1).

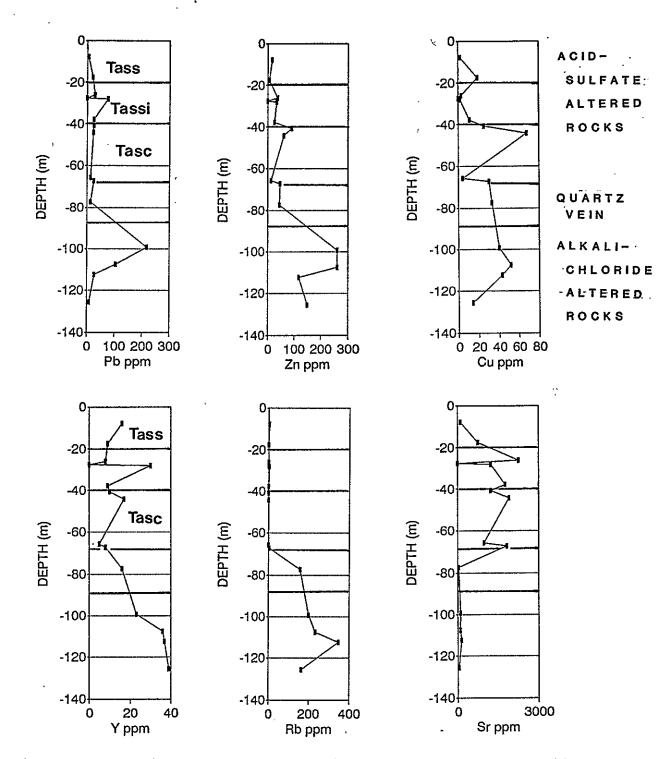

Figure 5.33—Alteration zonation and concentrations of selected trace elements with depth in USBM drill hole H10.

district (Fig. 5.34; Appendix 11.4). Many acid-sulfate altered rocks are also depleted in Rb (Fig. 2.24), Nb (Fig. 2.23), and Y (Fig. 2.23) relative to typical host rocks. Similar chemical trends are found at Telephone Ridge where the acid-sulfate altered rocks have higher concentrations of SiO₂ and lower concentrations of MgO, Na₂O, Rb, Zn, and Cu than underlying alkali-chloride altered rocks (Figs. 5.35, 5.36).

The acid-sulfate altered areas are typically zoned chemically, corresponding to the three mineralogical zones discussed earlier: central massive silica/chert zone, silicified zone, and outer clay zone. Three vertical sections through acid-sulfate altered rocks were sampled and analyzed for major and trace elements: USBM drill hole H10, west of Telephone Ridge (surface sampling only), and the south slope of Saddleback Mountain (surface sampling only) (Figs. 5.32, 5.33, 5.35, 5.36, 5.37).

The massive silica/chert zone (Tass) is characterized by >90% SiO₂ and is depleted in concentrations of most other elements (Figs. 5.32, 5.35, 5.37). The massive silica/chert zone is overlain by the silicified rocks at Saddleback Mountain and it overlies the silicified zone at all three localities. Maximum thickness rarely exceeds 20 m.

The silicified (Tassi) and clay (Tasc) zones are variable in chemical compositions. Silica and locally Pb decrease with depth away from the massive silica/chert zone, whereas Al_2O_3 , Fe_2O_3 , Na_2O , Ba, Cu, Zn, and Rb typically increase in concentration (Figs. 5.32, 5.33, 5.35, 5.36).

Changes in concentrations of many elements are erratic (Appendix 11.4). Indeed, some of the chemical trends previously discussed show erratic scatter in the data. This scatter may reflect differences in permeability which would allow or restrict flow of acidic fuids through the vertical section. The scatter also may reflect precipitation of secondary minerals during acid leaching. These chemical variations reflect complex fluid/rock interactions that would be expected in a near-surface hydrothermal environment.

6. DISCUSSION

6.1 Alteration

6.1.1 General environment of acid-sulfate alteration

Acid-sulfate alteration is recognized in four specific types of hydrothermal environments (Fig. 6.1; Table 6.1): (1) magmatic-hydrothermal (hypogene), (2) magmaticsteam, (3) steam heated, and (4) supergene (Rye et al., 1992). These four environments are distinguished by field relationships, mineral assemblages, chemical composition, and textures. A brief description of these four environments follows in order to better understand the origin of this alteration in the Steeple Rock district.

6.1.1.1 Magmatic-hydrothermal environments—The magmatic-hydrothermal acidsulfate altered environment is characterized by magmatic heat and significant magmatic components in the hydrothermal fluids. This type of environment has been termed "acidsulfate" by Heald et al. (1987), "high-sulfidation" by Hedenquist (1987) and White and Hedenquist (1990), "kaolinite-alunite" by Berger and Henley (1989), quartz-alunite by Cox and Singer (1986), and may also include the enargite-bearing gold deposits described by Sillitoe (1983). These deposits are fracture controlled, horizontally zoned away from the acid solution channels, and have ages coeval with intrusive activity. Fumaroles, silicification, and hydrothermal brecciation are common features. Extensive acid-leaching of alkalis and aluminum produces a core of vuggy or sugary silica (silica residue) surrounded by successive zones of quartz-alunite-kaolinite, quartz-pyrophyllite-kaolinite, and quartz-kaolinite grading into argillic and finally propylitized wall rock. Base- and precious-metals mineralization may be associated with the acid-sulfate alteration in this environment in some areas. This type of alteration overlies some porphyry copper and porphyry molybdenum deposits (Bove et al., 1990).

Acid fluids are produced by the disproportionation of magmatic sulfur with decreasing temperatures (i.e. cooling), as represented by the following reaction:

$$4SO_2 + 4H_2O \rightleftharpoons 3H_2SO_4 + H_2S.$$

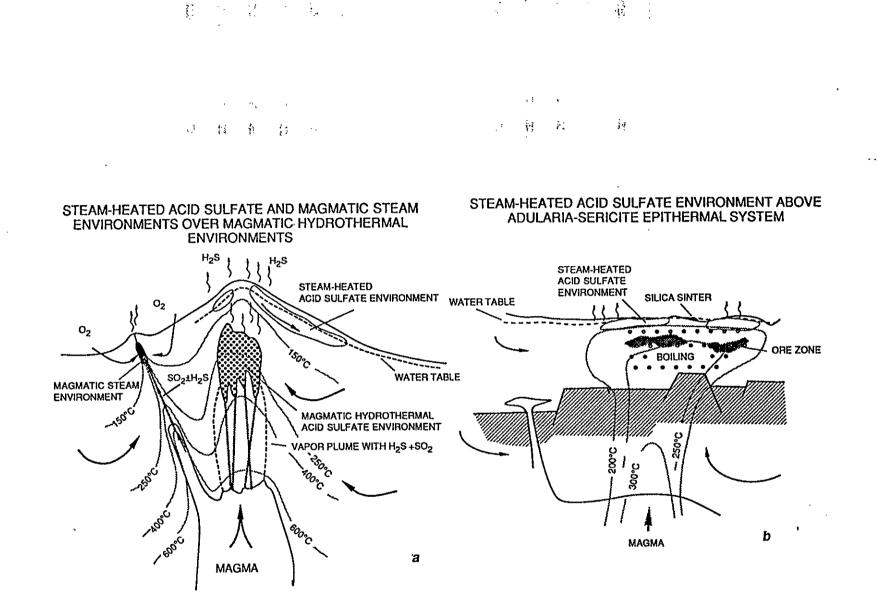

Figure 6.1 - Diagramatic sketch of types of acid-sulfate environments. a) Magmatic-hydrothermal and magmatic steamheated environments. b) Steam-heated acid-sulfate environment above alkali-chloride (adularia-sericite) system. From Rye et al. (1992), modified from Henley and Ellis (1983).

	Magmatic- hydrothermal	Magmatic . stcam	Steam heated	Supergene
Genesis	hypogene	hypogene	supergene	supergene
Structural controls	fracture controlled	fracture controlled	paleotopography	paleotopography, fault controlled
Timing	ages coeval with intrusive activity and mineralization	ages coeval with intrusive activity	much younger than host rocks, cocval with mineralization	much younger than host rocks and mineralization
Characteristics	fumaroles, hydrothermal breeciation and eruptions, horizontal and vertical zonation of mineral assemblages, silicification, vuggy silica common	fumaroles, hydrothermal brecciation and eruptions, veins	sinters, vertical zonation, at water table	oxidation at surface, blanket-like horizons
Associated metals	As, Au, Ag, Bi, Te, Sn, Sb, \pm base metals	sulfides absent	Cu, As, Au, Ag deeper in system	either no mineralization or preserved mineralization from younger episodes
Alteration mineralization	alunite (>2 μ m, hetero- gencous composition), quartz diaspore, pyrophyllite, pyrite, enargite	monomineralic alunite veins, hematite, quartz, kaolinite	alunite (<2 μ m homogeneous composition), quartz, kaolinite, cristobalite, opal, chalcedony, jarosite, hematite	alunite (<2 μ m), quartz, kaolinite, halloysite, jarosite, iron oxides
Stable isotopes	δ ³⁴ S of alunite 10–18‰ greater than for pyrite, δD similar to magmatic water	δD similar to magmatic water	δD similar to meteoric water, $\delta^{34}S$ of alunite similar to associated sulfides	δD similar to meteoric water, low $\delta^{34}S$ of alunite (similar to $\delta^{34}S$ of pyrite)

Table 6.1-Summary of characteristics of environments of acid-sulfate alteration (from Rye et al., 1992; Thompson and Petersen, 1991; Henley and Ellis, 1983).

HCl is also common in magmatic systems and further decreases the pH. The decrease in pH can also be a result of cooling without boiling (Reed and Spycher, 1985). The acid fluids dissolve most of the primary minerals in a rock, leaving silica residue. Sulfate minerals are deposited in the resulting voids.

6.1.1.2 Magmatic-steam environment—Recent work by Rye et al. (1992) and Cunningham et al. (1984) identified the magmatic-steam environment as a form of acid-sulfate alteration which is dominated by a vapor phase of magmatic origin. This environment is characterized by coarsely-crystalline monomineralic alunite veins up to several meters wide (Fig. 6.1; Cunningham et al., 1984). These deposits are rare, but have distinct stable isotope characteristics indicating a magmatic source; only four areas were studied by Rye et al. (1992). The genesis of these deposits is poorly understood, but available data indicate high temperatures, low pressures, and formation at shallow depths (Rye et al., 1992). Representative reactions are:

$$H_2S + 3/2O_2 \Rightarrow SO_2 + H_2O$$
$$SO_2 + 1/2O_2 + H_2O \Rightarrow H_2SO_4$$

6.1.1.3 Steam-heated environment—Steam-heated acid-sulfate alteration occurs in the near-surface, upper levels of hydrothermal systems (Fig. 6.1), at or above the water table. These environments are characterized by sinter, acid-leached silica residue, vertical zonation, and are controlled by topography. Alteration is vertically zoned from a sinter at the top, downward to quartz-alunite to quartz-kaolinite to argillic and propyllitic altered rocks (alkalichloride alteration). Mineralization is absent in the altered area (Rye et al., 1992; Thompson and Petersen, 1991), but the alteration may overlie precious-metal mineralization which occurs at the boiling zone and possibly even deeper base-metal mineralization (Fig. 6.1b). The age of alteration is coincident with the age of underlying mineralization (Rye et al., 1992). Opal, jarosite, hematite, and chalcedony are common. The acidic fluids are formed by condensation of vapor and oxidation of dissolved H_2S , derived from deeper alkali-chloride waters, summarized by the following reaction:

$H_2S + 20_2 \Rightarrow H_2SO_4$

6.1.1.4 Supergene environment—Supergene acid-sulfate alteration is produced by the oxidation at or near the surface of sulfide-rich deposits and therefore can be overprinted on mineralization formed by other types of acid-sulfate environments. Supergene environments are characterized by quartz, alunite, disordered kaolinite, halloysite, jarosite, and hydrous iron oxides. The alteration typically is controlled by topography, forming blanket-like horizons, that underlie gossans. Base- and precious-metals mineralization is older than supergene alteration and secondary enrichment may be common. Acid fluids may also descend along faults and become heated forming deep, thick, fault-controlled highertemperature acid-sulfate alteration with alunite and pyrophyllite. These zones are difficult to distinguish from other types of acid-sulfate alteration, unless field relationships are preserved. The acid fluids are produced by oxidation of sulfides in the near-surface environment, represented by:

 $2\text{FeS}_2 + 7\text{H}_2\text{O} + 15/20_2 \Rightarrow \text{Fe}_2\text{O}_3 \cdot 3\text{H}_2\text{O} + 4\text{H}_2\text{SO}_4.$

6.1.1.5 Other environments—Alunite forms rarely in the sedimentary and metamorphic environments under restricted conditions. Alunite and jarosite form as precipitates of acid-hypersaline lakes in Australia (Bird et al., 1989; Alpers et al., 1992; Long et al., 1992). Mechanisms of precipitation are unknown, but stable isotope data are available and are similar to magmatic-hydrothermal alunite (Table 6.1). Alunite also occurs in some regolith profiles in Australia (Bird et al., 1989). Isotopic and other data led Bird et al. (1989) to postulate that alunite was formed by evaporative concentration of solutes in the regolith profile. Diagenetic, concretionary deposits of alunite occur in lagoonal sediments in Israel and Sinai (Goldberry, 1980). Alunite is formed by bacterial action on illite under anaerobic conditions, represented by:

 $KAl_2[OH_2Al_2Si_3O_{10}] + 4H^+ + 2SO_4^{-2} = 3SiO_2 + KAl_3(SO_4)_2(OH)_6.$

Alunite is known to form in modern hot springs (Raymahashay, 1969; Schoen et al., 1974); data from some of these deposits is classified as steam-heated environment by Rye et al.

(1992). Alunite-group minerals also occur in low-grade metamorphic schist in South Africa (Schoch et al., 1985), however isotopic data are not available from these deposits.

6.1.2 Stable isotope studies

. .

: 1.

1.1.

··· ··· ·

Although it is beyond the scope of this project to analyze samples for stable isotopes, Field (1966) reports sulfur isotope data for coexisting alunite and pyrite from the Bitter Creek area in the Steeple Rock district:

A Alam	δ^{34} S alunite ‰	δ^{34} S pyrite ‰
	12.5	-6.3
- the second	12.7	0.7

Stable isotope studies of alunite and pyrite can provide information on (1) the origin of the components, (2) process and rates of formation, (3) physical-chemical environments, and (4) temperatures of formation.

An extensive literature search was conducted on alunite and stable isotope studies of alunite deposits, in order to interpret Field's (1966) data. Different geologic environments of alunite formation were identified and previously summarized in section 6.1.1. From these references, 62 areas were found with sulfur isotope data and many of these areas also had data on oxygen and hydrogen isotopes (Table 6.2). Rye et al. (1992) was the primary source, although other references were found. If more than one analysis was reported for an area, the data were averaged and both the average and the range were listed in Table 6.2. Each deposit was classified as (1) magmatic-hydrothermal (hypogene), (2) magmatic steam, (3) steamheated, (4) supergene, (5) regolith, (6) diagenetic, or (7) acid lake by Rye et al. (1992) or specific author(s) from available geologic, mineralogic, and geochemical data. One natroalunite sample (no. 50) is included in Table 6.2. It is beyond the scope of this study to address any problems or discrepancies in classification of individual deposits. Two deposits, numbers 27 and 28, were not classified by the authors, and a steam-heated classification was assigned by this author on the basis of available data. It is also assumed that published stable

Sec

Some potential problems may exist with stable isotope studies of alunite. Alunite forms a solid-solution series and substitution of other cations is common (Brophy et al., 1962). Alunite is locally fine-grained and difficult (impossible?) to separate from coexisting (not always cogenetic) minerals (such as quartz, kaolinite) and the effect on stable isotope studies is unknown. Different stages of alunite may be difficult to separate, especially when in fine-grained rocks. Recrystallization of alunite, which may be difficult to detect, may affect the isotopic chemistry. The isotopic chemistry of alunite may change as a result of later fluid migration, which is common in near-surface epithermal environments.

Alunite is found in several diverse geologic environments formed by different mechanisms. Alunite is a common product of acid-sulfate alteration. Weathering of sulfide deposits can also form alunite (supergene environment). Alunite is also found in modern hot springs (Raymahashay,, 1969; Schoen et al., 1974), acid lakes (Bird et al., 1989; Alpers et al., 1992), sedimentary rocks (Goldberry, 1980), and low-grade metamorphic rocks (Schoch et-al., 1985). The majority of isotopic studies on alunite have been from the acid-sulfate environment, although some data exist from other environments (Table 6.2).

Early work by Field (1966) demonstrated the usefulness of stable isotope studies in differentiating between hypogene and supergene environments. Nearly identical isotopic compositions are found to exist between sulfate (i.e., alunite) and associated sulfides (i.e., pyrite) in the supergene environment. Dissimilarity of sulfur ratios between sulfate and associated sulfides supports a hypogene (i.e., magmatic-hydrothermal) origin. This is predicted by fractionation theory of sulfur isotopes and differences in sulfur bond strengths. Sulfate (i.e., alunite) will be enriched in δ^{34} S relative to coexisting sulfide (i.e., pyrite) in a magmatic-hydrothermal environment, provided that equilibrium is maintained. However,

fractionation of the sulfur isotopes does not occur in a supergene environment and the δ^{34} S is similar for both sulfide and sulfate (Field, 1966; Field and Lombardi, 1972). Rye et al. (1992) confirms the original observations by Field (1966) and provides additional stable isotopic data that can be utilized to differentiate between environments of formation.

The range in stable isotope values for various deposits can be shown by a high-low graph (Fig. 6.2) and is summarized in Table 6.3. δ^{34} S can be used with some reliability to distinguish magmatic-hydrothermal alunite from magmatic-steam, steam-heated, and supergene alunite, especially if the δ^{34} S values are high (above 13%). However, caution is advised.

Type of Deposit	No. in Table 6.2	δ ³⁴ S
Magmatic-hydrothermal	1-15	6-31
Magmatic steam	16-19	-3.9-2.7

Diagenetic	55	15.6-20.6
Acid lake	56-62	4.5-21.2

Table 6.3—Summary of range of stable isotope data from Table 6.1. All values are in ‰.

Figure 6.3 is a histogram of δ^{34} S averaged values (Table 6.2) and it is apparent that there is overlap of δ^{34} S values from different environments. This is shown nicely in the cumulative frequency curve in Figure 6.4, which shows a curve with a slight break in slope at δ^{34} S = 13‰ and 20‰. The first break in slope is interpreted to correspond to the δ^{34} S value above which magmatic-hydrothermal and sedimentary (i.e., acid lake, diagenetic, regolith) environments are represented. However, δ^{34} S values alone can not be used to distinguish between alunites formed in the other environments. Other stable isotopes must be used, but these data are not available for the Steeple Rock samples. Data from Steeple Rock (i.e. Bitter

TABLE 6.4—Alunite-pyrite δ^{34} S pairs and calculation of formation temperatures using fractionation factors from Ohmoto and Rye (1979).

.

Creek, Table 6.2) are consistent with formation in a magmatic-hydrothermal environment.

Sulfur isotope analyses of mineral pairs have potential for use as geothermometers, although several assumptions are required in using mineral-pairs for geothermometers. The mineral-pairs must be cogenetic and formed at the same temperature and from the same reservoir. The minerals must not have undergone any change in isotopic composition since formation. Fractionation factors must be available and have diverging slopes (Faure, 1986). Data in the literature are available for alunite-pyrite pairs (Table 6.4). It is difficult to be certain for each and every mineral-pair that the minerals were formed at the same time because the references did not provide enough information to ascertain that they were cogenetic, although it is assumed that they are cogenetic for this study. Calculated temperatures shown in Table 6.4 are derived using the fractionation factor listed below from Ohmoto and Rye (1979):

 $10^3 \ln \alpha_{\text{alun (SO4)-py}} = (4.86 \times 10^6 \times T^2) + 6.0$

where α is the fractionation factor and T is temperature in °K. Substituting the relationship

 $\delta^{34}S_{alun}$ - $\delta^{34}S_{py}$ = 10³ In $\alpha_{alun (SO4)-py}$

into the formula results in:

1

بر. دخت

1.5

• • •

.....

à

÷.,

4

$$\delta^{34}S_{atun} - \delta^{34}S_{pv} = (4.86 \times 10^6 \times T^{-2}) + 6.0.$$

Simplification and substituting $T^{\circ}C = T^{\circ}K - 273$ results in:

$$T(^{\circ}C) = \frac{2.205 \ x \ 1000}{\sqrt{\delta^{34}S_{AL} - \delta^{34}S_{py} - 6}} - 273.$$

Most of the calculated temperatures in Table 6.4 from sulfur isotopes from magmatichydrothermal alunites are reasonable; however some are too high (no. 5, 13). Two temperatures calculated from the Steeple Rock data (Bitter Creek) are 339°C and 538°C. The lower temperature (339°C) is a reasonable estimate of the maximum temperature of the alteration, and is consistent with the alteration mineral assemblage (Table 5.1). It is important to determine the temperature of formation from isotope pairs because the altered rocks in the Steeple Rock district do not have fluid inclusions that can be measured (section 4.2).

The available geologic, mineralogic, chemical, and isotopic data indicate that the acid-sulfate altered areas in the Steeple Rock district are a result of magmatic-hydrothermal fluids (Rye et al., 1991) as evidenced by the high δ^{34} S of alunite from Bitter Creek, the difference between δ^{34} S of cogenetic alunite and pyrite, mineral and chemical zonations (section 5) and the similarity in age of alunite with the host rocks (section 5, Table 2.1). Early hydrothermal systems developed consisting of alkali-chloride waters that interacted with the wall rocks to produce regional alkali-chloride alteration (White, 1981). Acid fluids were derived from magmatic waters by disproportionation of magmatic sulfate with decreasing temperatures and resulted in the acid-sulfate altered areas, which overlie alkali-chloride alteration. These features are similar to modern hot springs systems such as Norris Geyser Basin in Yellowstone National Park (White et al., 1988). High sulfidation gold deposits, yet to be discovered, may be associated with these areas in the district.

6.2 Mineralization

6.2.1 Boiling and mixing

Boiling has dynamic effects on the chemistry of a fluid and is commonly evoked to explain mineral deposition. Loss of even a small amount of steam and other gases results in a change in concentrations of metal complexes as well as other ions. Boiling results in loss of heat, an increase in pH, an increase in salinity, and a decrease in gas content (Reed and Spycher, 1985). For example, loss of CO_2 causes calcite to precipitate according to the following chemical equation:

$$Ca^{+2} + 2HCO_3^- \Rightarrow CaCO_3(s) + CO_2(g) + H_2O.$$

 CO_2 is typically lost to the atmosphere making this an irreversible process. As calcite precipitates, the concentrations of other ions change. Therefore, it is important to recognize

zones of boiling because as gases are lost, metal solubilities decrease and deposition occurs. Boiling is episodic in many systems.

Several indicators can be used to recognize boiling in the low-sulfidation epithermal veins in the Steeple Rock district. Bladed calcite (lattice texture) is almost always found in zones of boiling fluids in modern geothermal systems (Talloch, 1982; R. R. L. Browne, unpubl. report, Spring, 1992; Mitchell and Leach, 1991; White and Hedenquist, 1990; Hedenquist, 1991; Simmons et al., 1992) and is one of the more distinctive indicators of boiling. This texture is common in epithermal vein deposits and is found along the East Camp-Twin Peaks fault system (including the Blue Bell fault).

In most natural waters, cooling without boiling causes calcite to dissolve (Fig. 6.5; Fournier, 1985b). However, when an ascending carbonate-rich fluid boils as a result of cooling adiabatically, then calcite will precipitate due to loss of CO_2 (Fournier, 1985b; Cunningham, 1985). Once CO_2 is lost, the boiling stops but the cooler water continues to ascend, dissolving the calcite. Quartz is deposited as a result of cooling of hydrothermal waters (Fig. 6.6; Fournier, 1985a) and therefore quartz simultaneously replaces bladed calcite. The rising fluids begin to boil again (as a result of adiabatic cooling) and the process is repeated until CO_2 is completely removed from the system.

In the Steeple Rock district, bladed quartz pseudomorphed after calcite and bladed calcite (Fig. 4.13) are found at the top of the Summit vein (elevation 1865.3 m) as well as at depths of 358 m in drill hole B91–17 (elevation 1290.8 m). Thus boiling occurred over a total interval of 574.4 m near the Summit mine and is associated with gold-silver deposition. Elsewhere in the Steeple Rock district, bladed quartz and/or calcite are rare and, if present, occur as late stage mineralization.

The presence of vapor-rich and two-phase fluid inclusions in the same sample is also indicative of zones of boiling (Roedder, 1984; Shepherd et al., 1985). However, liquid-rich inclusions also can form in the boiling zone by necking of two-phase inclusions. Thus fluid inclusion data for boiling need to be carefully evaluated. In samples from Steeple Rock, only

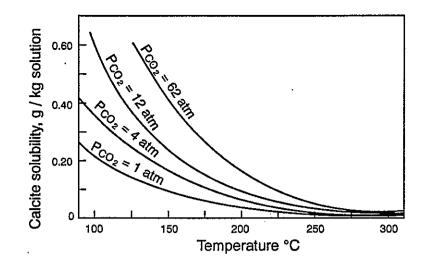

Figure 6.5 The solubility of calcite in water up to 300°C at various partial pressures of carbon dioxide (Fournier, 1895b; Ellis, 1959).

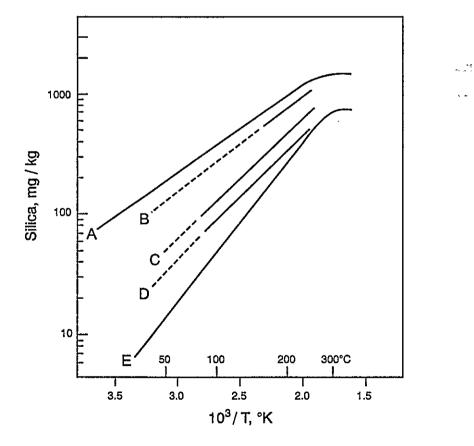

Figure 6.6 Solubilities of various silica phases in water at the vapor pressure of the solution. A= Amorphous silica, B= Opal-CT, C= α -Cristobalite, D= Chalcedony, E= Quartz (Fournier, 1985a).

a few contain both vapor-rich and two-phase inclusions and typically the vapor-rich inclusions are secondary inclusions (i.e., younger fluids). Therefore fluid inclusion evidence for boiling in the Steeple Rock district is inconclusive (section 4.2).

Additional mineralogic evidence for boiling includes (1) abundant quartz deposited as a result of cooling of supersaturated silica fluids (Fournier, 1985a), (2) veins of adularia as a result of an increase in pH resulting from boiling (P. R. L. Browne, unpubl. report, Spring. 1992), and (3) deposition of primary hematite as a result of oxidation of the fluids at the water table (Simmons et al., 1992; Cunningham, 1985). All of these features are present within the precious- and base-metal veins in the Steeple Rock district suggesting that boiling is a possible mechanism for mineral deposition, but not necessarily the only mechanism.

Cooling and mixing trends are difficult to determine in epithermal systems because they are not well defined by available data. Isotopic studies are required to define cooling and mixing trends and even isotopic data can be ambiguous. Fluid inclusion data can be used to indicate possible cooling and mixing trends (Shepherd et al., 1985). A plot of temperature vs. salinity of fluid inclusion data from Steeple Rock samples (Fig. 6.7) is consistent with cooling and mixing trends (Shepherd et al., 1985), but the effects of dilution and boiling are complex and specific models can not be derived from fluid inclusion data alone (Hedenquist and Henley, 1985).

6.2.2 Pressure and depth estimates

Data from fluid inclusion studies are widely used to estimate pressure and depth (Roedder and Bodnar, 1980). Two types of data are required to provide estimates of pressure at the time of formation of the fluid inclusions and presumably the host mineral: (1) composition of the fluid inclusions and (2) thermodynamic and geochemical data for the composition and temperature range of the fluid inclusions. These data are not always known exactly, thereby making any calculations of pressure and depth suspect.

The compositions of fluid inclusions from the Steeple Rock district are not known

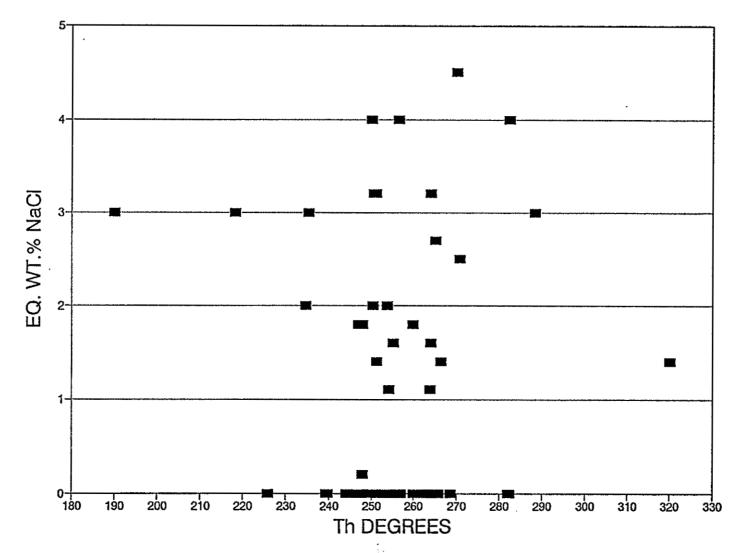

Figure 6.7 - Plot of temperature vs. salinity of fluid inclusions in quartz from the Steeple Rock district. This shotgun pattern is typical of cooling and mixing of fluids.

• •

307

exactly. Last-ice melting temperatures indicate that calculated salinities are less than 5 eq. wt. % NaCl. Preliminary gas analyses of fluid inclusions from the district indicate anomalously high contents of CO_2 and H_2S are present locally (Ruff, 1993; Ruff and Norman, 1991); however, exact quantities are unknown but presumed low because most two-phase inclusions contain less than 30% gas by volume. Therefore it is assumed that most fluids which deposited epithermal vein minerals in the district were probably 0–5 eq. wt. % NaCl with only trace amounts of gases. The presence of bladed calcite in certain areas formed by boiling suggests that locally CO_2 contents may have been relatively high.

The minimum pressure which a fluid can have is its vapor pressure at any given composition and temperature. If the confining pressure falls below its vapor pressure, then the fluid will boil. The maximum pressure which a fluid can have is due to the weight of the overlying rocks (the lithostatic pressure), although it is possible to have overpressures from tectonic or other stresses. If the fluid is open to the surface via faults or cracks, then the confining pressure is due to a column of the overlying fluid or hydrostatic pressure. Typically the lithostatic pressure is greater than the hydrostatic pressure.

In a simple H_2O -NaCl system, assumed for the veins in the Steeple Rock district, the estimated depth can be determined by using calculations and boiling curves by Haas (1971). From fluid inclusion studies, the veins in the Steeple Rock district were deposited at temperatures between 240 and 320°C (Fig. 4.20, 4.21). Therefore, the Steeple Rock veins were emplaced at minimum depths of approximately 360–1300 m, assuming hydrostatic pressures (Fig. 6.8). This range in depths is reasonable because the Dark Thunder Canyon formation and lava flows of Crookson Peak most likely were present above the epithermal veins for a total approximate stratigraphic thickness of 1300 m.

Once the depth is determined, the pressure can be calculated from the following formula (Shepherd et al., 1985):

$P = H\rho g$

Where P = pressure (bars), H = depth (m), ρ = density of overlying material (1.00 gcm⁻³

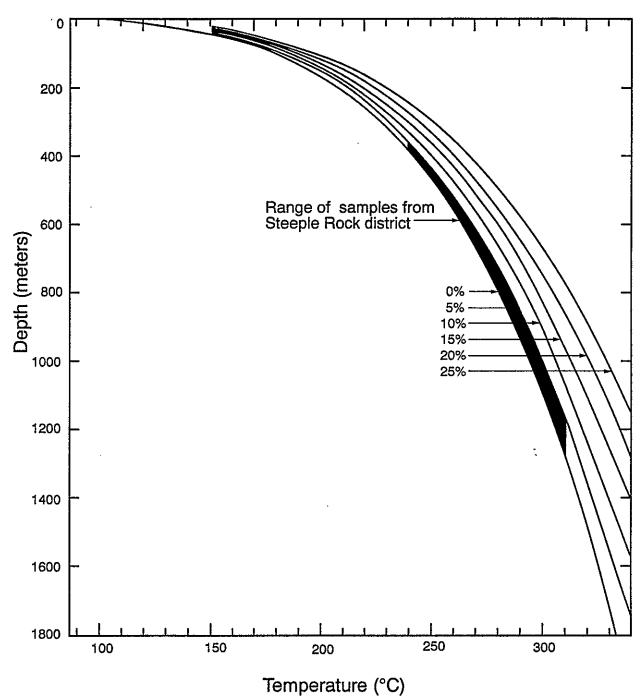

Figure 6.8 Boiling point curves under hydrostatic pressure for H_2O liquid (0 wt. percent) and for brine of constant composition given in wt. percent NaCl. The temperature at 0 meters of each curve is the boiling point for the liquid at 1.013 bars (1.0 atm) load pressure which is equivalent to the atmospheric pressure at sea level. From Haas (1971).

for hydrostatic and 2.70 gcm⁻³ for lithostatic overburden), and g = gravitational constant (981 dynes cm⁻²). Note that 1 bar = 10⁶ dynes cm⁻². Therefore approximate pressures of the formation of the veins in the Steeple Rock district are between 35 and 128 bars.

It must be emphasized that these pressure and depth estimates are only approximations because several assumptions exist. Furthermore, epithermal systems constantly seal and unseal, therefore the veins may be subjected to both hydrostatic and lithostatic conditions and overpressures may also occur. Epithermal systems are constantly changing, trarely in equilibrium, and dynamic.

However, from these calculations it is apparent that the veins in the Steeple Rock district formed at low pressures (<150 bars) and near the surface at shallow depths (<1.5 km). These estimates are typical of epithermal gold-silver districts throughout the world.

6.2.3 Geochemical constraints

Ŧ...

Certain constraints on the geochemical and thermodynamic evolution of the epithermal vein deposits in the Steeple Rock district can be determined using the geologic, mineralogic, geochemical, and fluid inclusion data presented in sections 2 through 5 in conjunction with published experimental and theoretical geochemical and thermodynamic data. Detailed computer modeling of various data is possible (Reed and Spycher, 1985), but is not utilized here because it is time consuming and tedious and requires additional data not available for the Steeple Rock district. In addition, textural evidence of the Steeple Rock veins is consistent with a dynamic and constantly changing physical and chemical evolution, which increases the complexity and decreases the ultimate reliability of computer modeling.

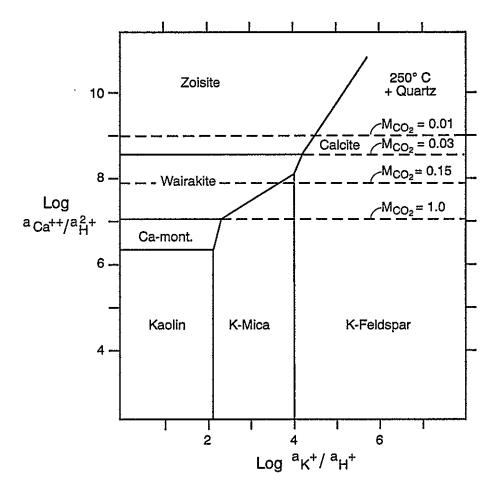

The epithermal veins in the Steeple Rock district were deposited from low salinity fluids (<5 eq. wt. % NaCl) at temperatures between 240° and 320°C (Fig. 4.20, 4.21, 4.22). Pressures were relatively low (<150 bars, section 6.2.2). Deposition probably occurred under complex and constantly changing cycles of boiling, cooling, and mixing at shallow depths (<1500 m; sections 6.2.1 and 6.2.2). Fluids, although low in total gas

content, probably contained elevated concentrations of CO_2 and H_2S as gases.

The veins consist predominantly of quartz which indicates that the fluids were supersaturated in silica (Fournier, 1985a; White and Hedenquist, 1990). Such supersaturated solutions generally indicate that large and rapid changes in the physical and chemical conditions of the fluid will occur and will ultimately affect the capacity of the fluid to transport and deposit ore minerals (Fournier, 1985a). Textures in vein samples from the Steeple Rock district suggest that some quartz was originally amorphous silica (section 4.1.2.1) and gold can be carried as a colloid with the amorphous silica (Herrington and Wilkinson, 1993). Therefore the transport and deposition of ore minerals is strongly dependent upon the solubility of silica with time.

The veins in the Steeple Rock district also consist of varying amounts of illite, adularia, calcite, and chlorite. Geochemistry of chlorite in epithermal systems has not been examined and thus chlorite will be ignored in this study. However, the presence of abundant illite and lesser amounts of adularia (K-feldspar) has important geochemical implications. Illite typically forms from acidic to slightly acidic solutions, depending upon the potassium concentration (Fig. 6.9; Henley, 1984; Reed and Spycher, 1985; Browne and Ellis, 1970). If the fluid is concentrated in CO_2 as well as Ca^{++} , then calcite will precipitate instead of the calc-silicate minerals (Fig. 6.9; Browne and Ellis, 1970). As the fluid evolves, the temperature most likely decreases, resulting in boiling, and resulting in an increase in pH. Thus deposition of illite may be followed by subsequent deposition of K-feldspar (adularia). This suggests that the Steeple Rock mineralizing fluids were probably acidic to slightly acidic and evolved toward neutral pH.

All types of veins in the Steeple Rock district typically contain pyrite and varying amounts of chalcopyrite, galena, and sphalerite. This mineral assemblage has important implications on the oxygen and sulfur fugacities. From the pH range established by the illite/adularia assemblage (3.5 to 5.6 at 250°C) and assuming a high to moderate potassium concentration, then the oxygen fugacity range can be estimated as log $fo_2 = -41.8$ to -30 (Fig.

ŗ,

• • •

,

Figure 6.9 Activity diagram for the principal phases in the system CaO-Al₂O₃-K₂O-H₂O at 250°C. Dashed lines repressent stability fields of calcite at different molarities of CO₂. Modified from Browne and Ellis (1970) and Henley (1984).

6.10; Barton, 1984). Then the sulfur fugacity can be estimated as log $a_{s2} = -12.5$ to -8.5 (Fig. 6.11; Barton, 1984). From this approach, it is apparent that the Steeple Rock mineralizing fluids were acidic to lightly acidic to neutral pH and had low to moderate oxygen and sulfur fugacities. These conditions are typical of low-sulfidation epithermal deposits (Table 1.1).

As the fluid evolved, the temperature decreased, pH increased, and the fluid became more oxidizing. This is consistent with the deposition of late adularia and primary hematite veins. Also influx of additional fluids probably occurred.

6.2.4 Relationship of mineralization to rhyolite intrusives

A common association between epithermal veins and rhyolite intrusions exists in many districts in the world (Cox and Singer, 1986; Buchanan, 1981; Burt and Sheridan, 1987). In the Steeple Rock district, some epithermal veins are related spatially to rhyolite dikes, especially in the Vanderbilt Peak (Alabama, New Years Gift, Laura, Jim Crow, Imperial mines), Apache Box, and Twin Peaks (Twin Peaks mine) areas. Locally, rhyolite dikes cut epithermal veins. However, in other areas of the Steeple Rock district, rhyolite intrusives are not present in the immediate vicinity of epithermal veins (East Camp, Summit, Bank mines). Mineralogic and geochemical data and statistical analyses described in sections 3 and 4 are consistent with, but not conclusive of, a genetic relationship between rhyolite intrusives and epithermal veins in the Steeple Rock district. Additional data supporting a rhyolite association include: (1) the tremendous amount of quartz deposition in the veins is best attributed to a rhyolitic magma rather than an andesitic magma, (2) the spatial association between the rhyolite dikes and epithermal veins, and (3) the epithermal veins are closer in age to the rhyolite intrusives than to the andesitic volcanism. However, this genetic association requires additional study.

6.3 District Zoning

6.3.1 Introduction

Systematic changes in the mineralogy, chemistry, and/or physical and chemical conditions within a mining district are referred to as district zoning. Zoning is also observed in much larger regional areas (regional zoning) and smaller, local areas (mine or deposit zoning). These systematic changes reflect changes in evolving fluids with time and distance from the source and provide excellent guides to ore deposits as well as to enhance our understanding of the genesis of ore deposits. By integrating and piecing together available data, district patterns emerge which are interpreted to represent district-wide zonations.

District zoning in epithermal districts is commonly difficult to interpret because the epithermal systems are dynamic and constantly changing. Overprinting of multiple epithermal (or geothermal) systems may also occur. In the Steeple Rock district, distribution of alteration assemblages, production, and vein mineral assemblages indicates that district zonations are partially preserved.

6.3.2 Alteration

Alkali-chloride alteration is common throughout the Steeple Rock district. Mineral assemblages containing epidote are indicative of deposition from fluids at temperatures greater than 200°C (Simmons et al., 1992) and are found at depth and near the epithermal veins in the Steeple Rock district. Mineral assemblages containing mordenite and smectite are indicative of lower temperatures (less than 180°C; Simmons et al., 1992) and are found distal to the epithermal veins (Fig. 6.12, 6.13).

Areas of acid-sulfate alteration are scattered throughout the Steeple Rock district (Fig. 5.4). The larger areas occur along the East Camp-Twin Peaks, Carlisle, and Bitter Creek faults. Sulfur isotopic data and mineralogy suggest maximum temperature of formation of 200–340°C (section 6.12; Fig. 5.1). Two areas are spatially associated with epithermal veins: Telephone Ridge area near the Carlisle and Center mines and Summit area near the Summit

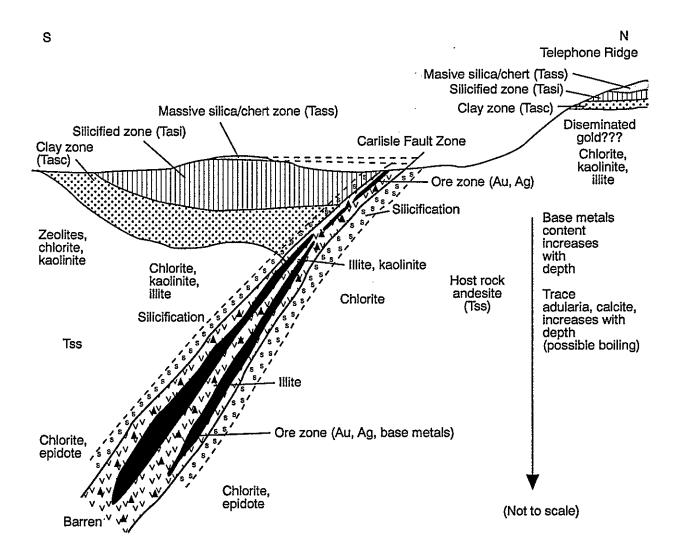

Figure 6.12 Relationship between alteration and vein deposits along the Carlisle fault (modified in part from Weacp drill data).

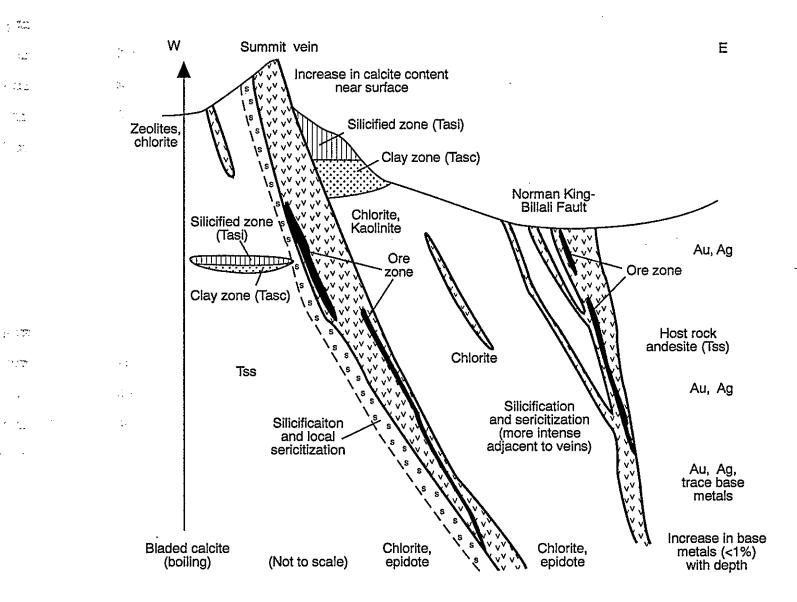

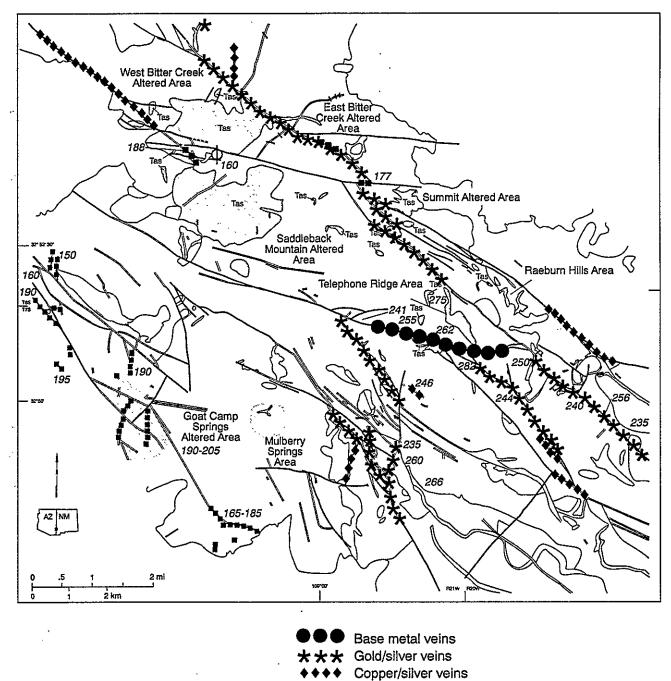

Figure 6.13 Relationship between alteration and vein deposits along the East Camp-Summit fault

and Bank mines (Fig. 6.12, 6,13). Acid-sulfate alteration caps or overlies base-metal veins at the Carlisle and Ontario mines and overlies precious-metal veins at the Bank mine. Furthermore, the Goat Camp Springs area is associated with fluorite veins.

Drilling at Telephone Ridge, Raeburn Hills, and Summit areas revealed minor intervals of disseminated gold mineralization. This acid-sulfate alteration overlies alkalichloride alteration and locally mineralized veins. The drilling data, mineral assemblages, age reltionships, and zonation (section 5.3) suggest that the acid-sulfate altered areas may represent separate surface hydrothermal systems (i.e. hot springs, geysers) that are likely connected at depth, similar to modern geothermal fields (such as at Yellowstone and New Zealand; Elder, 1981). These acid-sulfate altered areas may overlie undiscovered epithermal vein deposits, similar to those at Carlisle mine or overlie undiscovered, disseminated gold deposits (Fig. 6.12).

6.3.3 Epithermal vein mineralization

Base-metal vein deposits (>10% base metals) with significant gold and silver contents occur only along the Carlisle fault, between the Carlisle and Ontario mines and possibly westward into section 2. This area may well represent the center of the district (Fig. 6.14). Stratigraphically the Center-Carlisle deposits and the gold-silver veins at East Camp and Summit are the same. Outward from the Carlisle-Center mines, low-sulfidation goldsilver veins occur along northwest- and north-trending faults which contain little or no base metals (<1%). The gold-silver veins along the East Camp-Twin Peaks fault system are associated with bladed calcite or bladed quartz after calcite. These deposits are not spatially associated with any rhyolite intrusives, but the gold-silver deposits in the vicinity of Twin Peaks and Vanderbilt Peak in the western portion of the district are associated with rhyolite intrusives. On the fringes or outer margins of the district, copper-silver veins occur, locally grading with precious-metal veins, and the outermost zone is represented by fluorite and manganese veins (Fig. 6.14). Late-stage fluorite was also deposited in local areas of base- and

precious-metal deposits.

6.3.4 Fluid inclusion data

Collectively, fluid inclusion data, especially temperature of homogenization, provide additional information on district zoning. The highest temperatures of homogenization in fluid inclusions come from sphalerites from the deeper levels of the Center mine (Table 4.2; 288–325°C). Some of the higher temperatures of homogenization of fluid inclusions in quartz also come from the Carlisle-Center mines area (Table 4.1, Appendix 11.7). Furthermore, the temperatures of homogenization increase with depth at the Carlisle-Center and Alabama mines (Table 4.1, Appendix 11.7). Fluid inclusion data are consistent with the center of the epithermal system located in the Carlisle-Center mines area.

Two or more centers of fluorite mineralization can be interpreted from fluid inclusion data of fluorite. The bimodal distribution of temperatures of homogenization (Fig. 4.22) is consistent with two centers of epithermal activity. The highest temperatures of homogenization are from fluorite from mines and prospects in the Goat Camp Springs area and the Forbis and Luckie mines (average 190–205°C, Fig. 6.14; Appendix 11.7). Temperatures of homogenization decrease away from the Goat Camp Springs area: Rattlesnake mines average 165–185°C, Fourth of July mines average 155–170°C, and Daniels Camp mines average 190°C (Table 4.3, Fig. 6.14). In the Bitter Creek area, temperatures of homogenization in fluorite from the Bitter Creek drill hole (BC1) are lower (160°C).

These data suggest that a second center of fluorite mineralization may occur north of Bitter Creek. This temperature difference could also be accounted for by variations in lateral fluid flow and/or mixing.

There are insufficient data to determine the significance of the Twin Peaks mine and prospects at Apache Box. The veins at the Twin Peaks mine and Apache Box could be part of the precious-metal zone centered at the Carlisle-Center mines or they could represent one or more separate systems. The fluorite veins in the Bitter Creek area could be part of either system or a third independent system.

These data along with distribution of alteration (section 5), production (section 3), and mineral assemblages (section 4) suggest at least three possibilities. The fluorite and manganese mineralization represents the outer margins of an epithermal system centered at the Carlisle-Center mines. Alternatively, the fluorite mineralization could represent the top of separate epithermal systems that may grade into precious- and base-metals with depth. These separate epithermal fluorite systems could also be barren of metal mineralization. A combination of these hypotheses is also possible.

6.4 Paragenesis

Field observations, petrographic studies, descriptions of drill core, and other geologic data have resulted in a paragenetic sequence of events in the Steeple Rock district (Figs. 6.15 and 6.16). The paragenesis of alteration and mineralization can be divided into six stages: premineralization, four mineralization stages (stage 1, stage 2, stage 3, late), and post-mineralization. Two paragenic models are consistent with the geologic data: a episodic model (Fig. 6.15) and a continuous model (Fig. 6.16).

The pre-mineralization stage is characterized by regional and successive multiple periods of silicification and alkali-chloride and acid-sulfate alteration with deposition of disseminated pyrite. Intensity and rank of alteration varies according to physical and chemical conditions. Permeability of the altered rocks decreased as alteration increased, because secondary minerals filled the void spaces (section 5.5). The presence of coexisting epidote and chlorite at depth in alkali-chloride altered rocks indicates that temperatures ranged as high as 240°-300°C (Beaufort et al., 1992; Arnorsson et al., 1983; Simmons et al., 1992). Locally in the Steeple Rock district, steam-heated condensates formed at temperatures of 200-340°C and produced acid-sulfate altered areas near the surface, above the alkali-chloride altered rocks (section 6.1). Mineral and textural zoning (Figs. 6.12, 6.13) and limited isotopic data (Table 6.2; Field, 1966) suggest that this acid-sulfate alteration involved magmatic sources (i.e.

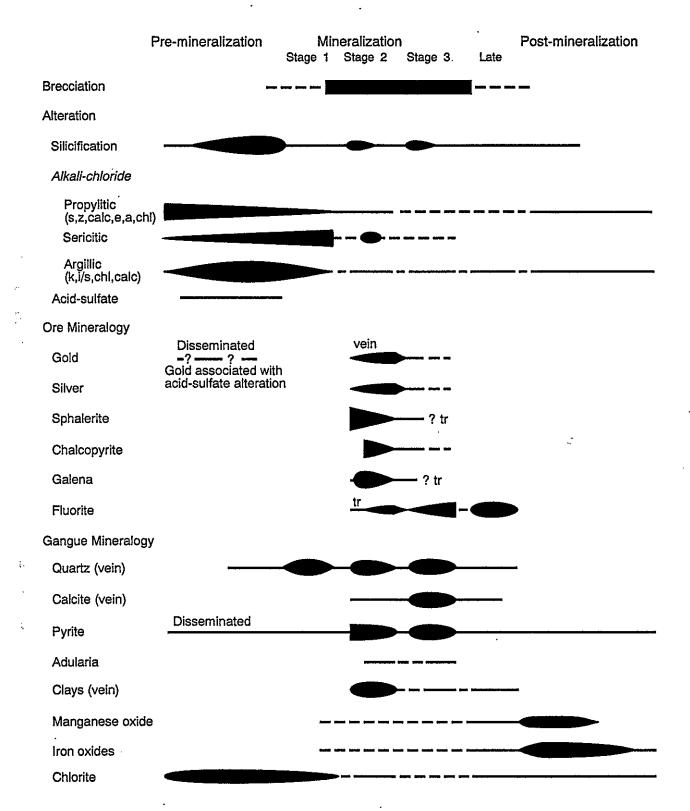

Figure 6.16 Simplified paragenetic sequence of events in the Steeple Rock District, assuming continuous alteration, mineralization and brecciation. s-sericite, z-zeolite, calc-calcite, e-epidote, a-adularia, chl-chlorite, i/s-illite/smectite, k-kaolinite hypogene origin). The potential for high-sulfidation disseminated gold deposits related to the acid-sulfate alteration is fair to excellent. Faulting and brecciation of this early alteration followed. Fragments of the altered rocks dominated by quartz, chlorite, and pyrite occur in the mineralized veins. Locally along the East Camp-Twin Peaks and Carlisle faults, acid-sulfate altered rocks were offset and placed adjacent to deeper-level alkali-chloride altered rocks (Maps 1, 2). The faults were subsequently filled with younger mineralization.

The mineralization period is divided into four stages, each stage may be separated by a period of brecciation: stage 1, stage 2, stage 3, and late mineralization (Fig. 6.15). However, brecciation could also have been continuous throughout the four mineralization stages (Fig. 6.16). Figure 4.12 illustrates the four stages of mineralization in one boulder. In general, stage 1 is characterized by white to gray to green chalcedonic to microcrystalline, barren quartz and pyrite, which occurs as breccia fragments within Stage 2 veins or occurs as thin bands along the contact with the host rock. Textures suggest that some chalcedony may be recrystallized amorphous silica (section 4.1.2.1). Stage 2 is the main ore-bearing event and consists of banded, rhythmically-layered, and brecciated quartz with gold, silver, and sulfides forming thin black to blue bands (Fig. 3.6) in a gangue of fluorite, calcite, adularia, clays, hematite, chlorite, and silicification. In some areas, stage 2 veins are brecciated and cemented by stage 3 quartz (Fig. 4.12). Stage 2 veins crosscut stage 1 veins. Recrystallized chalcedony or amorphous silica is rare in Stage 2, but occurs as small fragments interstitial to vein quartz. Multiple periods of this rhythmically-banded sulfide-quartz deposition occurred locally; however, detailed paragenesis is complex and only simplified in Figures 6.15 and 6.16. In some veins, sphalerite was deposited first prior to chalcopyrite as evidenced by replacement textures and chalcopyrite disease. Galena and pyrite were deposited after chalcopyrite. However, in other veins all four sulfide minerals coprecipitated (Fig. 4.7). Fluorite, calcite, and additional quartz were deposited during the waning stages of stage 2 mineralization, because these minerals occur in bands within the center of the stage 2 veins. Stage 3 mineralization is characterized by quartz, calcite, pyrite, and local adularia, clays,

chlorite, and iron and manganese oxides, which crosscuts stage 1 and 2 veins. Locally gold and silver mineralization with a trace of base-metal sulfides were also deposited. Temperatures of all stage 2 and 3 veins ranged from 240 to 330°C (Tables 4.1, 4.2, 4.3; Figs. 4.20, 4.21, 4.22). The temperature of stage 1 veins is unknown, but presumed to be <300°C on the basis of mineralogy. Late stage mineralization consisted of lower temperature fluorite (Table 4.3), drusy quartz, calcite, pyrite, clays, chlorite, and iron and manganese oxides in veins crosscutting stage 1, 2 and 3 veins, vugs, fractures, and other open spaces.

The mineralization stages were followed by post-mineralization alteration and oxidation (Figs. 6.15, 6.16). Alkali-chloride alteration with deposition of pyrite occurred. Thin veins of quartz-chlorite, quartz-calcite, and quartz-hematite crosscut mineralizing veins and older altered rock (Fig. 5.2, 5.3). Oxidation of near-surface base-metal veins occurred locally and may have concentrated gold and silver in some places by supergene enrichment processes. Some oxidation is currently active, especially at the Carlisle mine where nantokite and chalcanthite are forming along the adit walls. The pH of water in the Carlisle adit is 2.5–3.5. Iron and manganese oxides are also a result of this final alteration.

6.5 Age of alteration and mineralization

The age and duration of these six stages of alteration and mineralization are uncertain and are based upon a few age determinations (Table 2.1) and field relationships (section 2, Map 1). Alkali-chloride alteration probably began as soon as the permeable flows were emplaced and cooled as convective geothermal systems developed in response to high heatflow produced by continuing andesite and/or rhyolite volcanism during the Oligocene (section 5.2). Acid-sulfate alteration is closely related to alkali-chloride alteration (section 5.3). One age date of a quartz-alunite sample from Saddleback Mountain (acid-sulfate altered Summit Mountain formation) is reported as 31.3 Ma (Hedlund, 1993) and represents a maximum age of the acid-sulfate alteration and of the upper flows of the Summit Mountain formation. An additional age date of a relatively unaltered andesite from the Summit Mountain formation is also reported as 31.3 Ma (Hedlund, 1993). However, younger rocks are also altered by acidsulfate fluids in the Steeple Rock district and these rocks are 27–28 Ma or younger (ash-flow tuffs, sedimentary rocks, and andesites of the Dark Thunder Canyon formation; Table 2.1; Fig. 5.7).

Most modern geothermal systems have durations of activity of less than 3 million years, and most are less than a few hundred thousand years (Table 6.5; P. L. R. Browne, unpubl. report, Spring 1992). However, the activity in the Steeple Rock district spanned at least 3-4 million years. It was unlikely that one single hydrothermal system was active in the district. Multiple hydrothermal systems of unknown duration were probably active intermittently in the Steeple Rock district at least between 31–27 Ma and perhaps even more recently. The distribution (Figs. 5.4, 6.12, 6.13), zonations (section 5), and timing of alteration and vein mineralization (Table 2.1, section 2) are consistent with different periods of hydrothermal activity. The acid-sulfate alteration is clearly offset and cut by younger mineralized faults. These convective systems would develop in permeable rocks in response to continuing periods of volcanism followed by periods of nonvolcanism in the area. Migration of systems throughout time from one area to another probably occurred as well.

The age of epithermal mineralization is also uncertain. Epithermal veins fill faults that cut the Tertiary volcanics in the Steeple Rock district, the youngest of which are lava flows of Crookson Peak dated as 27.6 Ma (Hedlund, 1990c). Wahl (1983) reports that adularia from the East Camp vein has an age date of 18 Ma, but provides no additional data. Adularia from the Mogollon district, northeast of the Steeple Rock district (Fig. 1.1), has an age date of 18 Ma (³⁹Ar/⁴⁰Ar; W. C. McIntosh, pers. comm. December 1992). Since the adularia in both districts may be younger than the metal mineralization, these age dates are probably minimum ages. The adularia occurs late in stage 2 and in stage 3 mineralization in the Steeple Rock district. In Mogollon, the adularia occurs as late crystals on the quartz breccia (personal observation). It is also interesting to note that the second stage of supergene enrichment at the Tyrone porphyry copper deposit occurred at 19.5 Ma (Cook, 1993) and a similar age is

reported for the second stage of supergene enrichment at the Morenci copper porphyry deposit (S. S. Cook, pers. comm. February 1993).

In the Steeple Rock district, epithermal veins in some areas are spatially related to rhyolite dikes. Some rhyolite dikes in places offset some epithermal veins (Maps 1, 2). Wahl (1983) reports an age of a rhyolite dike as 18 Ma, but provides no additional data. Hedlund (1990a) reports an age of 21.4 Ma (fission track on zircon) from the quartz monzonite which intrudes the rhyolite of Steeple Rock (Table 2.1). A vitrophyre from a rhyolite dome west of Saddleback Mountain has an ³⁹Ar/⁴⁰Ar age of 25.3 Ma (Table 2.1; W. C. McIntosh and R. Appelt, pers. commun. Aug. 1993). Other ages of rhyolite intrusives in the Mule Creek-Summit Mountains area range from 28.7 to 17.7 Ma (Table 2.1). Therefore, epithermal veins in the Steeple Rock district are probably between 27 and 18 Ma and may be closer to 20 to 18 Ma in age.

6.6 Tectonic Setting

Many epithermal districts in southwestern New Mexico and the United States occur along ring-fracture zones of mid-Tertiary calderas (Fig. 1.1; Buchanan, 1981; Rytuba, 1981). However, there is no evidence to support a caldera in the vicinity of the Steeple Rock district, contrary to earlier interpretations (Biggerstaff, 1974; Elston, 1978). However, the Steeple Rock district lies in a tectonically active area that was dominated by a succession of dynamic and sometimes rapidly changing plate tectonic settings since Precambrian times, and especially since the Laramide period of compressional tectonics. Each tectonic period had lasting effects (section 2.3.1), but the most important events affecting the area are the more recent.

The Steeple Rock district lies on the southern edge of the Mogollon-Datil volcanic field (late Eocene-Oligocene), on the northern edge of the Burro uplift (Laramide), and near the intersection of the west-northwest-trending Texas and northeast-trending Morenci lineaments. Although only Oligocene-Miocene rocks are exposed in the Steeple Rock district, the regional faults have a trend similar to Laramide structural features and the Texas and Morenci lineaments. These major regional structural features probably reactivated throughout geologic time and in the Steeple Rock area may have acted as conduits and controlled emplacement of magma and subsequent hydrothermal activity.

The Burro uplift probably defines the northern edge of the Texas lineament in western New Mexico which remained a highland throughout most of geologic time. Paleogeographic and isopach maps suggest it was a highland from the Cambrian to the Cretaceous (Ross and Ross, 1986). Cretaceous marine sedimentary rocks onlap Proterozoic granitic rocks at Riley Peaks, south of Steeple Rock as well as in the northern Burro Mountains (Drewes et al., 1985). The Cretaceous rocks at Riley Peaks are relatively thin (<300 m; Hedlund, 1980b), suggesting that much of the Burro uplift was a highland prior to Laramide time (Drewes, 1991). However, a thicker section of Cretaceous rocks could have been deposited on the Burro uplift and subsequently been uplifted and eroded during the Eocene. The Virden Formation (Eocene; Elston, 1960; Hedlund, 1990b) consists of fluvial sediments that contain large boulders of Proterozoic granite, presumably eroded from the Burro uplift. The northern Burro uplift is probably part of the Morenci uplift of Cather and Johnson (1986) during the Eocene and may have been a source of sediment to the Eocene Baca Basin.

As Laramide compressional tectonics ceased, mid-Tertiary extensional tectonics began. In the Datil-Quemado area, this transition occurred at about 36 Ma. In the Steeple Rock area, this shift in tectonic styles is marked by eruption of bimodal volcanism at about 34 Ma with the emplacement of the andesite of Mud Springs, andesite of Mt. Royal, and rhyolite of Steeple Rock. From about 34 Ma to 27 Ma, as much as 2440 m or more of bimodal volcanic rocks were deposited in the Steeple Rock district on the northern Burro uplift, followed by intrusion of rhyolite dikes, and domes, and plugs from 28 to 17 Ma (section 2). It is speculated that this extensive pile of volcanics may have resulted in subsidence of the northern Burro uplift and was uplifted during late Tertiary as part of Basin and Range faulting.

The Texas and Morenci lineaments are defined by primarily structural features,

although Laramide copper porphyries also occur along the Morenci lineament. Epithermal deposits tend to form on the flanks of these lineaments (Fig. 1.1, 2.2). The lineaments are reactivated, deep crustal flaws that locally control emplacement of magma and subsequently hydrothermal fluids. These hydrothermal fluids migrate onto edges of highlands such as the Burro uplift and ultimately form epithermal deposits, for example, in the Steeple Rock district. Even today many hot springs in southwestern New Mexico occur over Laramide uplifts and along regional structures (Witcher, 1988), suggesting that Laramide structures have controlled regional heat-flow ever since.

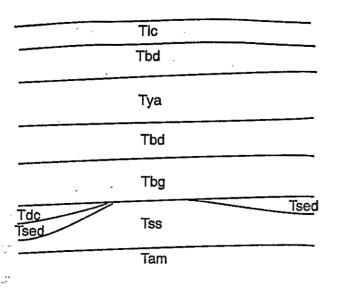

6.7 Geologic History

The Steeple Rock district occurs in a tectonically complex area. Regional lineaments and faults localized and controlled magmatic activity and subsequent hydrothermal fluids. Andesites, basaltic andesites, ash-flow tuffs, rhyolite intrusives and volcaniclastic rocks were deposited during a series of cyclic volcanic events from approximately 34 Ma to at least asyoung as 17 Ma (event 1, Fig. 6.17; Table 2.1). Minor rhyolite intrusion and extensive faulting may have occurred as early as 28 Ma, if not before (event 2, Table 2.1).

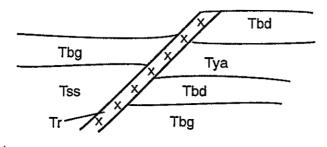

An older hydrothermal system developed in response to high heat flow produced by regional and local volcanism at approximately 31 Ma and younger (event 3, Fig. 6.17). More than one system probably developed in different localities and at different times; some systems may have migrated from one locality to another. This is supported by the complex and overlapping vents found in some of the altered areas (section 5). Regional alkali-chloride alteration affected most of the district during these events. Locally, acid-sulfate alteration, possibly associated with disseminated gold deposits (high sulfidation) yet to be discovered, occurred at or near the surface and was probably accompanied by hot springs and geysers. The abundant hydrothermal brecciation and presence of fossil fumaroles in the altered areas is supportive of this surface activity. Similar environments occur in modern geothermal systems, for example Norris Geyser Basin at Yellowstone National Park (White et al., 1988), Bacon-

2.) Minor faulting and possible intrusion of rhyolites.

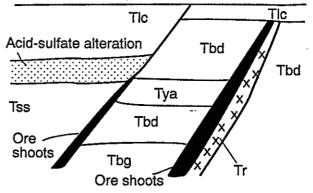

3.) Regional alteration (~ 31 Ma and younger).

4.) Burial (?), faulting and intrusion of rhyolites.

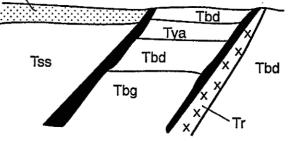

5.) Epithermal veins (mineralization stagelow sulfidation).

6.) Regional alkali-chloride alteration, erosion, and possible uplift.

Acid-sulfate alteration

Manito in the Philippines (Reyes, 1990), and Wasotapa in New Zealand (Simmons et al., 1992).

Faulting occurred after this alteration event because some areas of acid-sulfate alteration have been offset (event 4, Fig. 6.17; Maps 1, 2). A second hydrothermal system developed, probably in response to continued rhyolite intrusive activity. Low-sulfidation epithermal vein deposits (mineralization stage, Figs. 6.15, 6.16) formed along these faults and are associated with syn-mineralization alkali-chloride alteration (event 5; Fig. 6.17). Some ore shoots are capped by older acid-sulfate alteration, whereas other ore shoots cut acid-sulfate alteration (Figs. 6.12, 6.13). Some ore shoots are spatially associated with rhyolite intrusives (Map 2). Other geologic data (fluid inclusion analyses, section 4.2; mineralogy, section 4.1; and geochemistry, section 4.3) suggest that epithermal veins formed by chemically complex and diverse fluids (see section 6.2). The deposits were formed from low salinity, acidic to slightly acidic to neutral pH fluids at temperatures between 240° and 320°C at relatively shallow depths (360–1300 m). Ore minerals precipitated as a result of cyclic periods of boiling, cooling, and mixing. Four stages of mineralization occurred: brecciation accompanied mineralization.

A third hydrothermal system developed and produced regional alkali-chloride alteration which overprinted older alteration and mineralization (event 6, Fig. 6.17). Erosion and possible uplift followed. Oxidation, supergene alteration, and weathering of some deposits occurred, however, most deposits were not affected by oxidation and supergene alteration as evidenced by the mineralogy and chemistry of the deposits (section 3).

6.8 Relationship of the Steeple Rock district to other epithermal deposits and modern geothermal systems

This study illustrates numerous similarities between the Steeple Rock district and other epithermal vein deposits and modern geothermal systems. Several compilations with brief descriptions of epithermal deposits have been previously published and the reader is referred to them for details (Moiser et al., 1986, North and McLemore, 1986, 1988; Buchanan, 1981; Hayba, 1983; Heald et al., 1987; Hayba et al., 1985; White and Hedenquist, 1990; Rye et al., 1992). Numerous modern geothermal systems have likewise been examined and descriptions have been published (Mitchell and Leach, 1991; Browne, 1978; White, 1981; Elder, 1981). There are three common factors controlling the occurrence of geothermal systems: (1) most occur in areas containing deep-seated intrusives that provide heat for convective hydrothermal systems consisting of meteoric, magmatic, and locally formation waters; (2) all are formed at shallow crustal depths in permeable rocks; and (3) all are located along major regional structures, including crustal lineaments and calderas.

. :

...

...

However, there are some differences between the Steeple Rock district and other epithermal deposits and modern geothermal systems. Many older epithermal mineral deposits are common in modern geothermal systems; for example, McLaughlin at Geysers-Clear Lake geothermal system (Donnelly-Nolan et al., 1993); Mesquite at the Salton Sea trough system (McKibben, 1991); and numerous gold districts in the Philippines geothermal systems (Mitchell and Leach, 1991). However, the Steeple Rock district is one example of the early development of a geothermal system with both alkali-chloride and acid waters that cooled and were followed by younger epithermal mineralization and even later regional alkali-chloride alteration. Consequently, other epithermal districts and areas of acid-sulfate alteration need to be thoroughly examined to determine the relationship between alteration and mineralization in time and space and to determine if more than one hydrothermal event occurred.

334

7. CONCLUSIONS

Integration of Steeple Rock and other data and the resulting interpretations indicate that the alteration and mineralization of the Steeple Rock district are a result of successive, multiple cycles of volcanic and geothermal activity which occurred sporadically from 34 to 17 Ma (section 2). These systems had variable hydrologic and geochemical constraints which gave rise to complex, superimposed alteration and mineralization assemblages seen in the district (sections 3, 4, 5). Exact timing and duration of these events is partly speculative and based upon published age determinations (Table 2.1) and field relationships. There is no supporting evidence that these events were continuous; instead the alteration and mineralization were probably episodic, waning, and migrating from one locality to another. While many older epithermal deposits occur in areas of modern geothermal systems (section 6.8), the Steeple Rock district is one example of the early development of a geothermal system followed by younger epithermal mineralization.

Available data suggest that the acid-sulfate alteration in the Steeple Rock district was produced in a magmatic-hydrothermal environment (section 6.1). Sulfur isotope data, including geothermometric calculations, strongly support a magmatic-hydrothermal origin. Furthermore, the mineral assemblages, chemical changes, zonation, intense silicification, hydrothermal brecciation and hydrofracturing, and the presence of fossil fumaroles are consistent with a magmatic-hydrothermal origin (section 5). Alkali-chloride alteration is more pervasive in the district than acid-sulfate alteration and surrounds and underlies the acidsulfate alteration (section 5). This relationship is also consistent with a magmatic-hydrothermal environment for both types of alteration.

Available data also suggest that the low-sulfidation mineralization in the Steeple Rock district was deposited by low salinity (<5 eq. wt. % NaCl), neutral to slightly acidic fluids at temperatures between 240° and 320°C and relatively shallow depths (360–1300 m) and at low pressures (<500 bars; section 6.2). Locally, arsenic, antimony and mercury values occur at elevated levels within the mineralization and alteration (Appendix 11.6, section 4.3). A

335

combination of alternating cycles of boiling, mixing, and cooling hydrothermal fluids was involved in forming these deposits. The veins were emplaced along pre-existing faults and are younger than the alkali-chloride and acid-sulfate alteration. Faulting probably occurred throughout the mineralization epoch as evidenced by multiple brecciation in the veins.

Some general guides to ore mineralization can be summarized from sections 3 and 4. Known epithermal mineralization occurs along prominent silicified and brecciated faults. Precious and base metals occur in banded and rhythmically layered and brecciated quartz within aggregates or thin black bands or streaks of sulfides. The best ore shoots occur at inflections of strike and dip of the fault, especially at the intersection of cross faults. Ore occurs below and within zones of boiling as evidenced by bladed calcite and bladed quartz pseudomorphed after calcite. Predominant gangue mineralogy consists of chlorite, pyrite, illite, amethyst, and coatings of mottramite and/or mimetite are common if the ore is oxidized. Mineralized veins consist of high gold and silver values as well as elevated lead and zinc, and to a lesser extent, copper (sections 3, 4.3). Elevated arsenic concentrations

¥

Regional structures probably controlled magmatic and volcanic activity (which resulted in areas of high flow) and subsequent convective migration of hydrothermal fluids (section 2, section 6.6). The district lies on the southern edge of the Mogollon-Datil volcanic field (late Eocene-Oligocene), on the northern edge of the Burro uplift, and near the intersection of the west-northwest-trending Texas and northeast-trending Morenci lineaments (Fig. 2.2). Furthermore, the Santa Rita lineament (New Mexico mineral belt) occurs to the southeast. Faulting in the Oligocene-Miocene volcanic rocks in the district parallels these regional features as well as older Laramide structures as a result of compressional tectonics. This suggests that the Mid-Tertiary extensional tectonic features may be along reactivated Laramide features, at least in part. These regional features represent deep crustal flaws and acted as conduits for and controlled magma migration, heat flow, and subsequent hydrothermal fluids. This study also resulted in a few additional observations concerning alteration and stratigraphy. Major and trace element analyses must be used with care in volcanic terranes in characterizing the igneous rocks because silica was introduced early in the alteration process (section 2.4). Some rocks called dacites, because of tiny but visible quartz, are actually andesite with secondary quartz filling small amygoidals and other open spaces.

At least four ash-flow tuffs are exposed in the district (section 2.2). Two of the tuffs were derived from the Bursum caldera in the Mogollon Mountains. The younger ash-flow tuffs are perhaps from younger, less known calderas to the west and south. Some of the ash-flow tuffs also may be from local rhyolite doming (Fig. 2.5). Understanding the origin and distribution of these tuffs will aid our understanding of extent of regional ash-flow tuffs from distal calderas.

The economic potential of the Steeple Rock district for discovery of base- and precious-metals veins is excellent (section 4.4). Current exploration and past production (section 3) suggest that most orebodies are several thousands to several tens of thousands of tons in size, but it is possible to discover larger orebodies. Numerous mineralized faults have not been adequately explored at depth. Faults in the Alabama Ridge–Jim Crow mine area contain detectable gold and silver values and represent one area of future exploration. Geophysical surveys, geochemical sampling programs, and extensive drilling programs are required to identify and delineate additional areas of mineralization. Locally, elevated arsenic concentrations form a halo above mineralized veins which may serve as an exploration guide. In addition, the district has some potential for development of high-sulfidation disseminated gold deposits associated with the acid-sulfate alteration. Alunite deposits, specialty clay deposits, decorative stone, and perhaps fluorite also may have some economic potential.

8. FUTURE RESEARCH

Recommendations for future studies are summarized below.

- (1) Geochronologic studies of vein deposits and alteration in the Steeple Rock area are needed to confirm age relationships described in this study (sections 4, 5). These studies will aid in better understanding of the time involved in epithermal systems and the formation of gold-silver epithermal deposits.
- (2) Stable isotope studies of acid-sulfate altered rocks and vein deposits are necessary to confirm an input from magmatic-hydrothermal sources, define patterns of fluid flow, and provide additional data on temperatures of formation (section 6.1). Analyses of alunite are especially important because alunite can provide age constraints, information on sources, and constraints in temperatures of formation.
- (3) Paleomagnetic, geochronologic, and geochemical analyses of rhyolite domes, plugs and dikes should be done to determine information on age, source, and possible relationship to epithermal vein mineralization (section 2.2).
- (4) Paleomagnetic analyses of altered rocks, especially acid-sulfate altered rocks are needed to determine original lithology and age constraints. Also these studies could be used to determine the effects of alteration on paleomagnetic data.
- (5) More detailed mineralogic analyses, on the gold-silver veins are needed to aid in recovery of the precious metals and to aid in grade control (section 4.1). What are the silver minerals and where is the gold and silver in the veins? This information may also refine the genesis of these deposits.
- (6) Detailed geologic mapping and geochemical analyses of future mines should be done to provide better guidelines on ore controls and further our understanding of the chemistry and origin of these deposits (section 3).
- (7) Experimental work on chalcopyrite disease in sphalerite needs to be performed. What is the origin of chalcopyrite disease in epithermal environments? Are the minerals coprecipitated or does chalcopyrite replace sphalerite? Does chalcopyrite disease affect

338

microthermometric measurements of fluid inclusions?

.

- (8) Detailed mapping, petrologic, and geochemical studies of the older volcanic rocks of Steeple Rock and Mt. Royal are necessary in order to understand in more detail the emplacement of these rocks, including the Steeple Rock dome (section 2).
- (9) Experimental studies involving chlorite, quartz, and calcite/dolomite are required at different pHs and temperatures to produce needed phase diagrams in order to begin to understand the significance of chlorite deposition in the epithermal environment.

11.1 APPENDIX 1

DESCRIPTION OF DRILL CORE

This appendix includes brief petrologic descriptions and chemical analyses of drill core from throughout the Steeple Rock district. Not all of the core was available for study and the descriptions presented here are a synopsis of available data. In some cases, there was insufficient time to examine all of the core that was available. Most of the core examined is diamond drill core, although some data are based on drill cuttings from reversed circulation drilling. Descriptions designated by * indicate holes examined for this study. Each interval is assigned to a specific formation as used in this study by the author. Samples were collected from drill core examined and data from these samples are in Appendices 11.2, 11.3, 11.4, 11.5, 11.6, and 11.7. Assay data are typically as reported by the corresponding company, although some samples were assayed for this study and are included. All depths are drill depths unless otherwise specified (i.e., have not been converted to true thickness or depths).

11.1.1 Carlisle - Center mines

Brief descriptions and summary of drill data (Tables 11.1, 11.2, 11.3, 11.4) from holes in the Carlisle and Center mines area are below. The USBM drilled 14 diamond drill holes in 1942 (Russell, 1947) and the core is stored at the USGS Core Facility in Denver, Colorado (see Fig. 3.4, 5.11 and Map 5 for location). Drill holes H-1 through H-8 were drilled on the 700 ft level. Weaco, Ltd. drilled 20 holes at the Carlisle mine and one hole at the Section 2 adit in 1991 (see Fig. 3.4, 4.25 and Maps 2, 5 for location of drill holes). Splits of the cuttings are on file at NMBMMR. R&B Mining Co. drilled 5 diamond drill holes on the 10th level (Map 4). All holes were in the Summit Mountain formation and were examined for this study. Dresser Minerals also drilled 12 holes at the Center mine (Map 4, 5), but the core is not available for study. HD = Hole declination in degrees. DI – Drill depth interval in meters.

Hole no.	HD	DI (m)	Description				
Holes dr	Holes drilled by the USBM (1942)						
H-1	-67	0-53.8	Dark gray to gray andesite porphyry (Summit Mountain formation) with thin stringers of quartz and sulfide veins. Epidote common in trace amounts.				
		53.8-56.5	Quartz breccia vein locally with small fluorite cubes (< 1 mm diameter).				
		56.5-103.6	Gray to green-gray andesite porphyry (Summit Mountain formation).				
H-2	-84	0-53.9	Gray andesite porphyry (Summit Mountain formation) with disseminated chlorite, epidote, and pyrite.				
		53.9-75.0	Green-gray andesite porphyry with abundant chlorite and pyrite.				
		75.0-79.4	Quartz breccia vein.				
		79.4-94.6	Green-gray andesite porphyry (Summit Mountain formation).				
H-3	-68	0-64.5	Gray andesite porphyry (Summit Mountain formation).				
		64.5-72.4	Quartz vein				
		72.4-	Green-gray andesite porphyry (Summit Mountain formation).				
H-4	-39	0-36.6	Green-gray andesite porphyry (Summit Mountain formation) with thin veins of quartz, calcite, chlorite, and pyrite.				
		36.6-44.8 44.8-49.4	Quartz breccia vein. Silicified green to green-gray andesite porphyry				
		49.4-82.7	with abundant chlorite and trace epidote. Green-gray andesite porphyry (Summit Mountain formation).

TABLE 11.2—Summary of drill data at the Carlisle mine by WEACO, Ltd., 1991. Holes were drilled by reverse circulation and only drill cuttings are available. Samples were typically taken every 1.5 m and assayed (few exceptions). Only selected assays of drill intercepts are reported here. Depths are drill depths. Note holes CR91-2, -10, -11, -14, and -15 did not intercept the Carlisle vein.

Table 11.4 - Summary of limited data of holes drilled at the Center mine by Dresser Minerals (file maps 1976, 1978). Depths are assumed to be true depths. AZ = Azimuth in degrees; HD = hole declination in degrees.

11.1.2 Alabama mine

Brief descriptions and summary of drill data (Table 11.5) from two holes drilled by Great Lakes Exploration, Inc. at the Alabama mine are below. Location of holes in Figure 2.19. The core is stored at NMBMMR. Az - azimuth in degrees. HD - hole declination in degrees. DI - drill depth interval.

Hole no.	Az	HD	DI (m)	Description
*A1	N76E	-45	0-34.7	Green-gray to gray, chloritized porphyritic to amygdaloidal andesite of Dark Thunder Canyon formation. Locally cut by veins of quartz, chlorite, pyrite, and epidote.
			34.7-37.6	Silica-hematite breccia vein consisting of brecciated fragments of andesite and rhyolite in quartz- hematite matrix with local disseminated pyrite and other sulfides.
			37.6-44.1 44.1-56.1	Silicified intrusive rhyolite with local hematite. Green-gray, chloritized porphyritic to amygdaloidal andesite of Dark Thunder Canyon formation.
*A2	S75S	-65	0-61.9	Green-gray to gray, chloritized porphyritic to amygdaloidal andesite of Dark Thunder Canyon formation. Locally cut by quartz, chlorite, pyrite, and epidote veins.
			61.9-66.4 66.4-68.9	Brecciated andesite, bleached and hematized. Silica-hematite breccia vein consisting of brecciated fragments of andesite and rhyolite in quartz- hematite matrix with local disseminated pyrite and other sulfides. Visible gold reported. Cut by late calcite veins.
			68.9-70.1 70.1-77.4	Silicified rhyolite intrusive. Green-gray to gray, chloritzed and silicified porphyritic to amygduloidal andesite of Dark Thunder Canyon formation.

Table 11.5 - Summary of drill data at the Alabama mine by Great Lakes Exploration, Inc. (1991). Drill core from both holes examined for this study. AZ = Azimuth in degrees; HD = hole declination in degrees. Depths are drill depths.

11.1.3 Jim Crow-Imperial mines (Queenstake Resources, Ltd., 1984, 1987).

.

Below are brief descriptions of the drill core and a summary of drill data is in Table 11.6. Core from holes J84-2 and J84-3 were were examined for this study. Remaining descriptions are from unpublished reports by Queenstake Resources, Inc. Formation names in parentheses. HD = hole declination in degrees; DI = Drill depth interval.

Hole no.	HD	DI (m)	Description
J84-1	-60	0-25.3	Amygdaloidal andesite flows (Dark Thunder Canyon formation).
		25.3-56.6	Lithic-rich younger ash-flow tuff, top is poorly welded, whereas the rest of the unit is densely to moderately welded.
		56.6-74.7	Green-gray amygdaloidal andesite flows. Chloritization increases with depth (Dark Thunder Canyon formation).
		74.7-111.2	Quartz-sulfide veins in silicified hematite breccia zone.
		111.2-111.6	Andesite altered to gray clay (andesite of Mt. Royal?).
*J84-2	-75	0-3.7	Rotary drilled-no core.
		3.7-21.3	Amygdaloidal andesite flows of Dark Thunder Canyon formation with chlorite, hematite and calcite.
		21.3-47.9	Lithic-rich, younger ash-flow tuff. Densely welded in center. Hematized zones.
		47.9-89.0	Amygdaloidal andesite flows of Dark Thunder Canyon formation with chlorite, hematite, calcite and local quartz.
		89.0-93.3	Quartz-sulfide veins in hematite quartz breccia veins.
		93.3-111.6	Andesite, silicified, Dark Thunder Canyon formation.
		111.6-124.7	
		124.7-130.8	Andesite of Mt. Royal.
*J84-3	-57	0-24.4	Amygdaloidal andesite flows of Dark Thunder Canyon formation with calcite, hematite, and chlorite.
		24.4-53.6	Lithic-rich, younger ash-flow tuff. Densely welded in the center. Hematized zones.
*J84-3		53.6-73.1	Amygdaloidal andesite flows of Dark Thunder Canyon formation with calcite, hematite, chlorite, and quartz.
		73.1-92.7	Quartz-hematite breccia with quartz-sulfide veins.
		92.7-93.6	Andesite of Mt. Royal(?).
J87-1 .	-60	0-18.3	Amygdaloidal andesite flows (Dark Thunder Canyon formation). Propyllic alteration. Veinlets of calcite, chlorite, quartz, and clay.

Table 11.6 - Summary of drill data at Jim Crow-Imperial mines by Queenstake Resources, Inc., 1984, 1987. AZ = Azimuth in degrees; HD = hole declination in degrees. *Assayed by NMBMMR chemical laboratory (zones in the younger ash-flow tuff). Depths are drill depths.

11.1.4 Summit area

The most extensive drilling in the Steeple Rock district has been along the East Camp-Summit fault from south of the Summit mine northwestward to north of the Mohawk mine. Inspiration Minerals, Inc. drilled 15 holes underneath the Apex-Summit workings and delineated additional ore (Table 11.7). Subsequently NovaGold Resources, Ltd. drilled along the vein in 1988–1989. In 1989 NovaGold entered a joint venture agreement with Biron Bay Resources, Ltd. and additional holes were drilled in 1990, 1991, and 1992 (Table 11.8). Biron Bay Resources, Ltd. is the controlling partner in the joint venture. Most of this drill core is available for study, however, only five holes were examined for this project due to time constraints. Three descriptions are presented here.

Hole no.	HD	DI (m)	Description

## 11.1.5 Telephone Ridge-Raeburn Hills areas

Limited drill data were available from holes drilled on Telephone Ridge by Pioneer Nuclear, Inc. in 1984 (Table 11.9) and in the Raeburn Hills area by FMC Gold Co. in 1988 (Table 11.10). Neither cuttings nor core were available. Location of drill holes in Figs. 5.7, 5.11, and Map 2. Both areas were drilled to located potential gold deposits related to the acidsulfate alteration. Brief description of drill core from Telephone Ridge from Pioneer Nuclear, Inc. maps is below.

Hole no.	HD	DI (m)	Description					
SRIC -45	0-4.2 4.2-45.7 45.7-49.7 70.1 75.0-153.6 153.6-349.9	Soil Bleached argilized acid-sulfate, silicified zones. Ash-flow tuff (Bloodgood Canyon Tuff??). Fluorite veins with pyrite. Altered ash-flow tuff or tuffaceous sediments. Green gray to dark gray andesite of Summit Mountain formation.						
SR2C	-60	0-26.2 26.2-60.0 60.0-86.3 86.3-97.2	Green-gray andesite of Summit Mountain formation. Maroon to green to gray acid-sulfate altered tuffs or andesite. Quartz veins cutting altered rock. Tuff.					
SR3C	-50	0-27.7 27.7-117.0 117.0-289.2	Green-gray andesite of the Summit Mountain formation. Acid-sulfate altered rock with thin quartz veins. Green-gray andesite of the Summit Mountain formation.					
SR4C	-50	0-20.0 20.0-?	Green-gray andesite of the Summit Mountain formation. Acid-sulfate altered rock. (Additional data not available.)

### 11.1.6 Bitter Creek BCl (Kennecott Co., sec. 20, T16S, R21W, 1954)

A brief description of available core from the Kennecott hole in Bitter Creek is below. The hole was drilled to a total depth of 746 m (Hedlund, 1990b), but some of the core is missing. This drill core is stored at the USGS core facility in Denver, CO, and was examined for this study because it provides the only subsurface data in the Bitter Creek area. The collar elevation, exact location, azimuth, and hole declination are unknown, but it is assumed that the hole was vertical. Approximate location of the drill hole is plotted on Map 2. It is possible that some of the missing core may represent altered or mineralized zones. Assays are not available, but several samples were collected and assayed for this study (Table 11.12). Data for samples collected are in Appendices 11.3, 11.4, 11.5, and 11.6. Depths are drill depths.

Hole No.	Hole declination	Depth interval (m)	Description
*BCl	vertical(?)	0-29	Core missing
		29-33.5	Gray to bleached yellow andesite porphyry of the Summit Mountain formation with chlorite altered zones and zones of disseminated pyrite (Appendix 11.3). Calcite veins.
		33.5-58.0	Core missing.
		58.0-62.2	Green-gray andesite porphyry with chlorite alteration; Summit Mountain formation.
		62.2-71.6	Core missing.
		71.6-82.6	Gray to brown andesite porphyry of Summit Mountain formation. Feldspars altered to white to yellow clay. Calcite veins.
		82.6-85.3	Green to colorless fluorite vein with some quartz, calcite, and manganese oxides.
		85.3-114.0	Green-gray andesite porphyry. Summit Mountain formation with thin veinlets (<2 cm wide) of quartz, calcite, galena, pyrite, sphalerite, chalcopyrite and fluorite. (Assays of a sample in Table 11.10.) Chlorite and mixed clays in host (Appendix 11.3).
		114.0-116.4	Brecciated zone (hematite, chlorite). Assays in Table 11.10.
		116.4-117.0	White clay zone.
		117.0-118.0	Green to colorless fluorite veins.
		118.0-177.4	Green-gray andesite porphyry, Summit Mountain formation, chlorite alteration. Pyrite disseminated throughout most of the interval.
		177.4-183.5 183.5-255.1	Missing core. Green-gray to black andesite porphyry of the Summit Mountain formation. Pyrite and chlorite throughout. Thin veinlets (<1 cm) of quartz, calcite, pyrite, chalcopyrite, galena, and sphalerite.
		255.1-258.5	Coré missing.
		258.5-277.7	Green-gray andesite porphyry, Summit Mountain formation. Chlorite alteration with disseminated pyrite. Veinlets. Some zones of black andesite porphyry.
		277.7-428.8	Green-gray andesite porphyry, Summit Mountain formation. Alteration minerals consists of epidote,

Hole No.	Hole declination	Depth interval (m)	Description
			chlorite, pyrite, and quartz (Appendix 11.3).
			Core missing.
			Green-gray andesite similar to above.
		446.5-449.2	Green-gray to red-brown andesite porphyry, Summit Mountain formation with hematite and carbonate alteration. Minor chlorite and epidote (confirmed by XRD, Appendix 11.3).
		449.2-477.3	
		477.3-480.3	White silicified zone. Assays of sample in Table 11.10.
		480.3-525.8	Green-gray andesite porphyry, Summit Mountain formation with chlorite, hematite, pyrite, and epidote.
		525.8-527.9	Brecciated and fractured andesite with quartz veins and hematite.
		527.9-549.2	Green-gray andesite porphyry, Summit Mountain formation with chlorite, hematite, pyrite, and epidote. Brecciated zones locally.
		549.2-561.4	Green-gray, lithic volcanic breccia (andesitic).
		561.4-577.3	Green-gray andesite porphyry, Summit Mountain formation with chlorite, pyrite, epidote, and calcite.
			Core missing.
		579.7-608.4	Green-gray andesite porphyry, Summit Mountain formation with chlorite, pyrite, epidote, calcite, and minor quartz.
		608.4-609.6	Gray silicified zone with disseminated pyrite.
			Core missing.
		615.7-633.3	Green-gray andesite porphyry, Summit Mountain formation with chlorite, pyrite, epidote, calcite, and minor quartz and fluorite veinlets (<2 cm). Silicified zones present.
			Core missing.
		649.8-741.2	White to green-gray, silicified andesite or dacite porphyry with chlorite, epidote, pyrite, and calcite. Veinlets of amethyst.
		741.2-746.0	Core missing.

## Appendix 11.4—Chemical analyses of host rocks

Major and trace elements of host rocks and altered rocks from the Steeple Rock district are given in this appendix. Analyses are by XRF except for mercury which is analyzed by cold fusion AA. CIPW Norms are calculated using PETCAL (Bingler et al., 1976). Major oxides are in percent (%); trace elements are in parts per million (ppm). CIPW Norms are in percent. Alteration intensity (alt. int.) is described in Chapter 5. Rock Unit refers to formation (Fig. 2.1). XRD and TS refers to analyses by x-ray diffraction and thin section description (Appendix 11.2). Sample locations are on Map 2.

Appendix 11.4a—Chemical analyses of rhyolite intrusives (by XRF, NNMMR). Fe₂O₃ is total iron calculated as Fe₂O₃. * From Hedlund (1990b). @ From Wahl (1980). ^From Bornhorst (1986, 1988). bd - below detection limit (Table 1.3).

#### Appendix 11.5-Chemical analyses of quartz veins.

Major and trace elements of quartz veins from the Steeple Rock district are given in this Appendix. Analyses are by XRF, except for gold and silver (fire assay), copper, lead, zinc, and mercury (AA). Methods, detection limits, and errors are discussed in section 1.5.4. Alteration intensity (ALT) is described in section 5.1. Rock unit refers to formation (Fig. 2.1). XRD and TS refers to analyses by x-ray diffraction and thin section description (Appendix 11.2). FI indicates analyses by fluid inclusion (Appendix 11.7). Sample locations are on Map 2. Major oxides are in percent (%); trace elements are in parts per million (ppm).

### **APPENDIX 11.6**

Chemical analyses of mineralized samples. Analyses in parts per million except for Au and Ag, which are in oz/ton and Fe, CaF₂ which are in percent (%). Sample locations are on Map 2. Analyses by Lynn Brandvold and associates or by Chris McKee (XRF), designated by *. Samples are selected grab samples, unless otherwise specified. See Table 1.3 for detection limits, methods of analyses, and % error.

## Summary of fluid inclusion data

Over 1200 temperatures of homogenization and salinity measurements were made on samples from the Steeple Rock mining district. Methods are in section 1.5.6. These data are summarized in Tables 4.1, 4.2, and 4.3. This appendix includes graphical representation of temperatures of homogenization by mineral host, individual mines, and groups of mines. A number of samples were grouped together according to geographic location as follows:

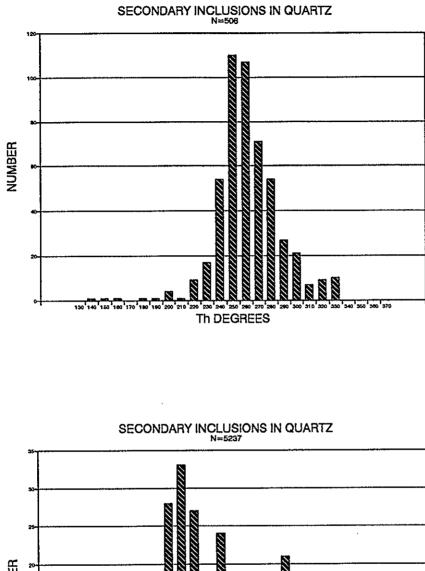

Geographic location	 Sample number
Carlisle fault (quartz) East Camp fault (quartz) Alabama–Imperial Rattlesnake mines (fluorite) Goat Camp Springs (fluorite) Luckie Mines Forbis mines	 400S, 404S, 182, Ontario, Center, 231 47, McDonald adit, 634 310, 434, Alabama DH1 472, 473 510, 516, 518, 536, 538, 545 559, Luckie No. 2 1043, 1041

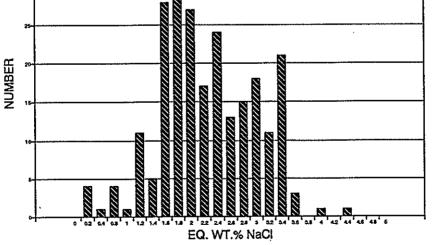

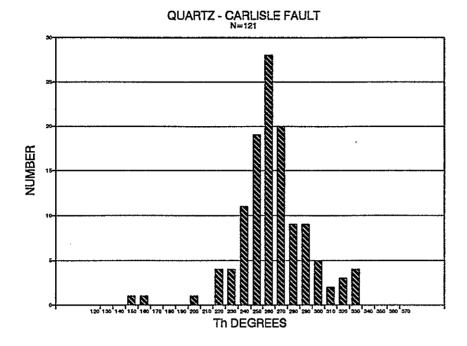

Plot of all primary inclusion data from all quartz samples.

467

Plot of all secondary inclusion data from all quartz samples.

FLUORITE - DANIELS CAMP MINES

### 14. CURRICULUM VITAE

Virginia T. McLemore (maiden name Hill) was born on June 11, 1955, in Baltimore, Maryland. She graduated from Woodlawn Senior High School, Baltimore, MD in June 1973 and entered New Mexico Institute of Mining and Technology (NMIMT), Socorro, NM, in the fall, 1973. She worked as an exploration petroleum geologist with Natural Gas Pipeline Co. of America from June 1975 to September 1975. She married James V. McLemore on May 29, 1976. After graduating from NMIMT with a B.S. in Geology and a B.S. in Geophysics in May 1977, she was an assistant field geologist (uranium exploration) for Urangesellscheft, USA, Inc. from May 1977 to September 1977. In the fall, 1977, she entered graduate school at NMIMT. Daughter Jennifer G. McLemore was born September 17, 1978. Virginia graduated from NMIMT with a M.S. in Geology in May 1980 and her M.S. thesis was entitled Geology of the Precambrian rocks of the Lemitar Mountains, Socorro County, New Mexico. In June 1980 she became a Uranium Geologist for the New Mexico Bureau of Mines and Mineral Resources (NMBMMR), where she is currently employed as an Economic Geologist. On December 9, 1980, daughter Christine E. McLemore was born. Since employment with NMBMMR, she has written numerous articles on the geology of New Mexico and contributed to several books. In August 1988 she attended the Penrose Conference on Anorthosites in Laramie, WY. She is a member of several societies including AIME-SME (Society for Mining, Metallurgy, and Exploration), SEG (Society of Economic Geologists), AEG (Association of Exploration Geochemists), GSA (Geological Society of America), and NMGS (New Mexico Geological Society). She is serving on and has served on numerous committees, chaired sessions at local and national conferences, and chaired or assisted with local and national field conferences. In January 1990, she entered the Graduate School at the University of Texas at El Paso.

Permanent address: 701 Caine, Socorro, NM 87801. This dissertation was typed by Lynne Hemenway.
