Origin of the Riley travertine
as constrained by the clay mineralogy of
acid- and EDTA-insoluble residues

by

James M. Barker, Industrial Minerals Geologist
New Mexico Bureau of Mines and Mineral Resources
Socorro, NM 87801

January 31, 1984

Introduction

The Riley travertine is an unusual and potentially economic limestone deposit of Plio-Pleistocene age in northwestern Socorro County, New Mexico (Fig. 1). This paper investigates the clay minerals present in the insoluble residues of the Riley travertine to constrain its origin.

The origin of the Riley travertine is controversial because of its highly varied morphology. Opinions vary widely and include playa-lacustrine deposition, pedogenesis (caliche), spring deposition (travertine), and pervasive secondary calcite formation (nonpedogenic calcrete). Previous work, covered in Barker (1983), which bears directly on this paper is summarized in Table 1. Earlier studies in the area of this report include Barker (1983), Chamberlin and others (1982), Massingill (1977), Kottowski (1962), and Denny (1940, 1941). The origin most supported is that of caliche deposit (pedogenesis).

The clay-mineral assemblages of proposed depositional environments of the Riley travertine can be used to constrain the possible origins. After reviewing over 300 published and unpublished references on calcrete and caliche, Goudie (1972) states that the clay mineral fraction, most frequently contains sepiolite and palygorskite (attapulgite) but may also contain other clay minerals. Based on this and other work summarized in Table 2, the presence or absence of attapulgite and sepiolite along with their relative abundance, favors some depositional environments over others.

Attapulgite = $MgAl_2(S_{14}O_{10})(OH)_2 \cdot 4H_2O$

Table 2: Summary of relationships among continental deposits of attapulgite (A) and sepiolite (S).

Geographic and geologic setting

The Riley travertine occurs in two main masses (north mesa and south mesa) centered approximately 6.5 km west and approximately 17 km south of the summit of Ladron Peak and east-southeast of Riley (Santa Rita), New Mexico (Fig. 2). The Riley travertine is intermittently exposed by local erosion of overlying Santa Fe Group sediments along mesa edges facing the Rio Salado.

The Riley travertine of north mesa underlies approximately 46 km² in T. 2 N., R. 3 W. and T. 3 N. R. 3 W. on the west flank of the Ladron Mountains. At south mesa, it underlies approximately 21 km² in T. 1 N., R. 2 W., T. 1 N., R. 3 W., T. 1 S., R. 2 W., T. 1 S., R. 3 W., and a small portion of the Sevilleta Game Refuge on the west side of the Silver Creek drainage.

Access to the study area is via graded roads from Magdalena (US-60) or from Bernardo (exit 175 on I-25). When dry, the Rio Salado provides secondary four-wheel-drive access to both north and south mesas. North mesa is approached most easily from the north on ranch roads bearing southeastward towards the western slope of the Ladron Mountains from the county road to Riley. The south mesa is reached most easily from the Hudgins Ranch road which intersects US-60 east of Magdalena. All of north mesa and most of south mesa are on the Riley 15-min quadrangle with the remainder on the Magdalena 15-min quadrangle. Preliminary 7.5-min quadrangles are available.

The Riley travertine is a relatively undeformed member of the Santa Fe Group (Barker, 1983) deposited between 1 and 3 m.y.

ago (Chamberlin and others, 1982). It descends in elevation from north mesa to south mesa and overlaps progressively younger (Paleozoic, Mesozoic, and Cenozoic) units to the south.

The Riley travertine ranges from massive to laminar with locally significant reworked, vuggy, algae-like, and fragmented portions. This varied morphology is interpreted by Barker (1983) as follows.

The limestone is the result of a nonpedogenic process producing proximal (surface and subsurface) and distal (subsurface) secondary carbonate deposits related primarily to lateral groundwater flow. The carbonate-charged water is interpreted to have been generated in Paleozoic limestones on the west flank of the Ladron Mountains and the southeast flank of Sierra Lucero in the late Cenozoic. These waters flowed over and through alluvial fans and other sediments into and down the axis of an elongate basin or valley draining southward. This drainage merged with an east-trending valley which drained eastward near the present latitude of San Lorenzo Canyon and emptied into the ancestral Rio Grande. Proximal spring, lacustrine, and reworked carbonate deposits were formed at the surface. They are contemporaneous with pervasive and expansive subsurface secondary calcite cementation of pre-existing host sediments. This depositional system is analogous in part to the ground-water calcrete (nonpedogenic) described in Western Australia by several authors (see for example Carlisle and others, 1978).

This model should yield clay-mineral assemblages that result from the depositional environment of the host sedimentary rocks or sediments and, therefore, that are varied. In contrast, one mode of formation would tend towards a single clay-mineral assemblage. If the Riley travertine is a caliche, attapulgite should be dominant over other clays. If it is an alkaline lacustrine-playa deposit, sepiolite should be dominant. A spring, fresh-water lake, or pervasive secondary origin should yield detrital clays -- such as illite, smectite, and kaolinite, typical for an arid

climate acting on a Paleozoic limestone substrate.

Sampling and experimental techniques

Seventeen samples of the Riley travertine were collected in March 1983. Preliminary data, including clay mineralogy of HCl (10%) insoluble fractions, are published in Barker (1983). Additional work was done in the fall of 1983 to generate more gently derived insoluble fractions. These samples were partially digested using very dilute acetic acid followed by warm EDTA solution. The clay-size fractions of the insoluble residues were then analyzed by X-ray diffraction (XRD) for clay and detrital mineralogy.

Samples of the Riley travertine were treated initially with dilute (0.25 M) acetic acid as described by Ostrom (1961). Because of the samples' high calcium carbonate content, this proved too slow. The samples were purged of acetic acid by washing and decanting with deionized water. A 0.2 M solution of EDTA was then used for digestion as described by Bodine and Fernalld (1973). This greatly sped up carbonate solution but at much greater cost in reagents. The EDTA procedure was modified slightly as described below.

Carbonate-solution procedures

Acetic-acid method--Samples of the Riley travertine

(approximately 150-gr) were scrubbed and washed thoroughly in deionized water. Then, they were crushed for 5 min in a Buehler concentric-ring vibratory crusher yielding a very fine carbonate

powder. Such a fine grind ultimately caused problems in both dissolving methods used, because much of the carbonate material begins as clay-size particles. These, plus the larger particles dissolved into the clay-size range just before particle extinction, yielding persistent clay-size carbonate residues on the XRD slides. This change from Ostrom's (1961) procedure is not recommended since clay-carbonate separation is not possible until all the carbonate is completely dissolved. I left coarser particles (1 cm +) to insure that carbonate was always present so the acid would be less likely to attack the clays. Ostrom's (1961) recommendation of a -60 mesh grind should be used, because the relatively coarse carbonate can be separated easily from the liberated clay-size material at any time during the dissolving process.

Acetic acid, mixed to 0.25 M concentration, was added to the samples, which were stirred periodically until reaction was complete. The spent acid was decanted, and a new charge of 0.25 M acetic acid added for as many iterations as needed. With materials as rich in carbonate as the Riley travertine, dozens of charges of acid would be needed at the 0.9-liter charge size utilized. Thus, an EDTA-based procedure was initiated part way through the sample-dissolving stage.

EDTA method--Chelation of carbonate by tetrasodium ethylenediamine tetracetic acid (EDTA) affords a method of carbonate solution that does not affect original clay mineralogy. The method described by Bodine and Fernald (1973) was used. Based on their charts, a 0.2 M EDTA solution (75 gm technical-

grade disodium EDTA in 1 liter deionized water at pH 12.5) was applied to the ground carbonate partially digested by acetic acid. The solution was heated to 90° C for 60 to 90 min using a continuous magnetic stirrer. After settling and decanting, a new charge of EDTA was added until the carbonate was entirely chelated. The problems caused by the very fine grind as described above were also present in this procedure.

After dissolution, decanting, and deflocculation, using deionized water only, the clay fraction was separated from the coarser insoluble particles. Standard clay-mineralogy techniques were then used as follows.

Following deflocculation, the dispersed clay was left undisturbed for 10 min. Then, eyedropper charges of the suspension were collected carefully from the topmost surface and deposited on glass slides until they were fully covered. Four slides of each sample were prepared as described above and then allowed to air dry overnight. The oriented slides thus derived are not useable for quantitative work because of size fractionation in the suspension column during drying. The larger kaolinites settle out first and then are masked somewhat by later mantling by the slower-settling smaller clays such as smectite or illite.

The slides were run on a diffractometer at 2° 2 θ /min from 38° to 2°02 . The slide was then glycolated at 60° C for 3 hrs and a second run was made as described above. The slides were then heated to approximately 300-330° C (some to 390° C) for 1 hr and run hot as described above, except the span was shortened to 15°-2° 2 θ . Controlled-humidity and cation-saturation runs were

not done.

Clay-mineral reactions during carbonate solution

Two problems possibly developed using the acetic-acid or EDTA digestion techniques. These are destruction of clays, such as illite or smectite, by excess acidity and the alteration of attapulgite-sepiolite by either excessively acid or basic conditions.

The work by Ostrom (1961) in proving his technique showed no alteration in acidic solutions (if less than 0.3 M) for randomly interstratified illite-montmorillonite, chlorite, illite, or kaolinite. He did not include attapulgite or sepiolite. Carroll (1970, pp. 43-44) states that attapulgite and sepiolite require alkaline conditions for survival and that they are decomposed by acid and won't survive below pH 7. Other workers suggest pH 3 as the threshold. In addition, Khoury, et al. (1982) predict that chlorite will form instead of attapulgite-sepiolite at high pH and high Mg and/or Al. This prediction is based on their interpretation of the work of Siffert (1962, in Khoury et al., 1982), who found that sepiolite precipitates at pH 8.5, trioctohedral smectite (mixed-layer kerolite-stevensite of Khoury et al., 1982) at pH 8.5-9, and talc plus trioctohedral smectite at pH above 9. The EDTA solution used has a pH of approximately 12.5, which is possibly high enough to alter sepiolite-attapulgite to mixed-layer kerolite or stevensite (chlorite) plus talc (Ebrl, et al., 1982). The XRD data suggest that no such conversion occurred during digestion of the Riley travertine since neither kerolite, stevensite, or talc were detected.

Bodine and Fernald (1973) evaluated the effects of EDTA treatment on clay minerals. They found no significant alteration occurred with treatment times under 4 hrs. They examined chlorite and illite (mixture), montmorillonite, and kaolinite. They did not determine effects on attapulgite-sepiolite. Glover (1961) implied that EDTA treatment was less destructive than acid treatment where clays were involved, but he studied no clays individually. Hill and Runnels (1960) made a similar suggestion.

The original digestion using 10% HCl (Barker, 1983) produced clay-size residues containing kaolinite, illite, and smectite in order of decreasing abundance (Table 3). Treatment with this concentrated a solution of HCl probably biased the clay data so a less chemically harsh dissolution technique was used for this study. The presence or absence of attapulgite or sepiolite is significant in the identification of depositional environment, and the HCl technique might have removed or altered them.

Clay-mineral analysis

The clay size fraction of the insoluble residues from eight samples of Riley travertine were analyzed by X-ray diffraction techniques. The samples were deflocculated by repeated rinsings with deionized water and 10-min centrifugation cycles. No deflocculating chemicals were used.

Standard oriented slides were prepared by sedimentation (Stokes Law) techniques with their inherent bias (Stokke and Carson, 1973; Gibbs, 1965, 1968). This bias precluded meaningful measurement of clay-mineral percentages, and many of the illite curves are masked by mixed-layer clays. Thus, the following

analysis is based on the presence or absence of significant clays rather than on relative abundance.

The XRD analysis was done on a Rigaku D-Max. Settings were copper fine focus at 40 KV and 25 ma. Slits were 1° divergence, 1° scatter, 0.3° receiving, and 0.3° monochromator. Each sample was run untreated followed by a glycolated run and heated (300° C and/or 390° C) runs.

Results

The mineralogy of the clay fraction, based on number of occurrences in the samples and in decreasing order is as follows:

- quartz
- feldspar (Na-Ca-K combined)
- kaolinite
- illite
- mixed-layer illite smectite (random and ordered)
- rhodochrosite
- amphiboles
- zeolite (clinoptilolite)
- vermiculite (masked)
- chlorite (masked)
- smectite (difficult to identify as masked)
- superlattice clay or ordered mixed-layer
(vermiculite-illite)

This is the mineralogy derived from acetic-acid/EDTA insoluble residues. In contrast, the harsher HCl-derived insoluble residues have a much simpler mineralogy in their clay-size fraction, as shown below:

Table 3. Qualitative X-ray diffraction analysis of the fine fraction (-230 mesh) of selected samples of the Riley travertine treated with 10% HCl. The clay peaks were very small except for kaolinite.

- quartz
- feldspar
- kaolinite
- illite
- amphibole
- smectite

The minerals described below are from the EDTA/acetic-acid procedure. Each mineral is described by characteristic and common peaks seen in the samples.

Quartz

Quartz is identified by its characteristic peak at approximately $26.7^{\circ} 2\theta$. A common peak also occurs at approximately $21^{\circ} 2\theta$ with some variability.

Feldspar

The feldspars occur from $27.5^{\circ} 2\theta$ to $28.1^{\circ} 2\theta$ with some variation depending on potassium, calcium, and sodium content. The various feldspars were not differentiated.

Kaolinite

Kaolinite is found in 85% of the samples examined. Peaks around $12.4^{\circ} 2\theta$, $20.5^{\circ}(+) 2\theta$, and $24.9^{\circ} 2\theta$ are typical. Kaolinite is a very stable clay so it is least affected by acid or EDTA techniques and, thus, is dominant in both suites of analyses.

Illite

Illite is as common as kaolinite (85% of samples), but its main peak at approximately $8.8^{\circ} 2\theta$ is masked by the broad illite-smectite mixed-layer "bump". Illite in untreated slides is typically represented by a "shoulder" on the mixed-layer

curve, which separates somewhat upon glycolation. The illite peak is greatly sharpened and enhanced by heating of slides because of recrystallization of the mixed-layer clay.

Mixed-layer Illite-Smectite

Mixed-layer clays occur in 70% of the samples as a broad bump between approximately $3^{\circ} 2\theta$ and $9^{\circ} 2\theta$. This range varies and usually includes a masked illite peak and often a masked vermiculite-chlorite one as well. The mixed-layer clays are frequently random, but one possible instance of an ordered mixed-layer clay was observed in sample 4. However, this could also be interpreted as a vermiculite or chlorite peak. Sample 4 has no heated run because of slide disintegration; consequently, a definitive answer is not possible. The broad mixed-layer peak shifts to a lower 2θ upon glycolation (lattice expands).

Rhodochrosite

Rhodochrosite (MnCO_3) is found in 85% of the slides, usually in trace amounts. It is recognized by a sharp peak at approximately $31.4^{\circ} 2\theta$. The Riley area is noted for high manganese values including a once-active mine at north mesa. The probable source rocks in the Paleozoic carbonates also have appreciable amounts of manganese (Table 5). Four samples with peaks at $31.4^{\circ} 2\theta$ were analyzed for MnCO_3 (Table 6). Measurements range from a trace to 0.25% manganese. Given the abundance of manganese and the close relationship between calcium and manganese carbonates, the presence of rhodochrosite is not unusual. Rhodochrosite is soluble in HCl, so it did not appear in the hydrochloric-acid treated samples (addendum 1).

Amphibole

I did not differentiate the various peaks from 10 to $11^\circ 2\theta$ but rather assigned them to the general class of amphiboles. Depending on composition, a range of peaks is possible, and the varied lithologies of provenance areas open possibilities beyond the scope of this paper.

Zeolites

A strong peak at $9.8^\circ 2\theta$ with a secondary peak at $22.3^\circ 2\theta$ indicates clinoptilolite. The presence of a zeolite in 25% of the samples is not unexpected, since these are very common sedimentary minerals in arid terranes. Zeolites form generally in alkaline ground-water conditions or in igneous rocks. Clinoptilolite is more indicative of a sedimentary origin but may be diagenetic on a small scale rather than representing large-scale alkaline conditions.

Vermiculite-Chlorite

Vermiculite (sample 5) or chlorite (sample 9) is indicated by a peak at 6.3 - $6.5^\circ 2\theta$. Neither was affected by glycolation, but, in one instance, the peak disappeared upon heating (vermiculite) but did not in the other (chlorite).

Smectite

Smectite may be present as a distinct phase but is masked by the broad mixed-layer illite-smectite peak.

Super lattice Clay

One sample showed a broad peak at $3.8^\circ 2\theta$ and a multiple at $7.6^\circ 2\theta$, which, when converted to d-spacing, yielded a clay most likely made up of vermiculite-illite. This clay did not expand much upon glycolation nor contract much upon heating (from $23^\circ 2\theta$

to $20.5^{\circ} 2\theta$ to $22^{\circ} 2\theta$).

Discussion

The data for the HCl digestion are in Table 3, and the data for the acetic-acid/EDTA digestion are in Table 4. The XRD plots are in addendum 1 (HCl) and addendum 2 (acetic acid-EDTA). X-ray fluorescence (XRF) plots of selected samples for their manganese content are in addendum 3.

Glass and others (1973) and Frye and others (1974, 1978) studied the Ogallala Formation in eastern New Mexico. The general regional geology is similar to that of the Riley travertine area. Both are underlain by Permian and Triassic rocks, often with identical units. The clay minerals they assigned to a "normal" detrital assemblage from such basement rocks were smectite, illite, and kaolinite. This assemblage is basically the same as that found in the Riley travertine insoluble residues. Based on this association, the Riley travertine has only a detrital clay component.

Attapulgite and sepiolite were not detected in the Riley travertine. The data in Table 2 can be used to differentiate the occurrence of attapulgite and sepiolite. These two minerals tend to be mutually exclusive. However, they often occur together during a transition, and this mixture represents slightly varying conditions at the interface between the stability fields for each.

Universal requirements for both attapulgite and sepiolite are relatively dry or dessicating conditions. The chemistry of these minerals requires high silica, high Mg, and high (but

restricted) pH. Table 5 shows the high Mg content of the regional carbonates. Ishphording (1973) has shown that attapulgite additionally requires high aluminum. Climatically, sepiolite occurs under drier conditions. Attapulgite has much greater resistance to weathering than sepiolite. Attapulgite is usually sedimentary, whereas sepiolite is sedimentary but also is common in igneous association. Since both require high magnesium and alkalinity, conditions may not have been correct. However, Glass and others (1973) and Frye and others (1974, 1978) found abundant attapulgite and sepiolite in certain facies dependent on environment. So attapulgite and sepiolite do occur in eastern New Mexico where source rocks and climate are very similar to northwestern Socorro County. Thus, the lack of attapulgite and sepiolite in the Riley travertine must be related to factors other than lack of magnesium, low alkalinity, etc. since they formed in eastern New Mexico under similar conditions.

The variable seems to be the environment of deposition. Attapulgite is primarily associated with soils while sepiolite is more common in alkaline lakes or playas (Table 2). Apparently, these environments were not present during formation of the Riley travertine, which is thus neither a soil nor an alkaline lacustrine deposit. This conclusion is in harmony with recent work (Barker, 1983).

The main 2- θ peaks for attapulgite (A) and sepiolite (S) are as follows:

A	8.4*(10)	13.75(3)	19.86(4)**	27.61(3)**	35.19(3)
S	7.3*(10)	11.91(2)**	19.77(3)**	20.60(2)**	26.52(2)**

* key line ** usually masked in Riley samples

(relative intensity)

The 10-intensity peaks are masked by the broad mixed-layer illite zone. In addition, many of the secondary peaks are masked by various other clay and nonclay minerals. Thus, a small amount of attapulgite or sepiolite could be present and missed. However, the basis for assigning a pedogenic or alkaline lacustrine environment to the Riley travertine is based on attapulgite or sepiolite dominating the clay mineralogy. Minor amounts of attapulgite and sepiolite overwhelmed by illite, smectite, kaolinite, etc. is nondiagnostic. For these reasons, I conclude that the Riley travertine was not formed as a soil or as an alkaline lake-playa deposit.

The illite-smectite-kaolinite suite does not define other environments conclusively. Therefore, the Riley travertine could be a spring deposit or a pervasive secondary carbonate deposit. The detrital clays could be deposited in a travertine during its deposition either by wind or, as circumstances permit, by fluvial activity. In contrast, during pervasive carbonate deposition, the clays are an artifact of the depositional environment the host sediments represent. Carbonate crystallization can destroy some silicates (including clays), so the initial host clay mineralogy cannot be known with certainty.

Summary

The origin of the Riley travertine is constrained by the absence of attapulgite and sepiolite. These clay minerals are associated with soils (caliche-calcrete) and alkaline lakes,

respectively, so the probability that these are the depositional environments for the Riley travertine is low.

The clay-mineral assemblage present is a typical detrital one for areas of New Mexico with Permian-Triassic bedrock. The vermiculite, chlorite, illite, mixed-layer illite-smectite, and kaolinite are not diagnostic and may represent either syngenetic minerals in a spring deposit or minerals representative of the host-rock depositional environment if a pervasive calcite origin is correct. The presence of vermiculite and chlorite is uncertain pending more detailed sampling.

Because of the preliminary nature of this report, some additional work must be done to confirm the conclusions reached. Additional work includes, but may not be limited to, the following:

- 1) Dissolve by EDTA a calcareous rock with attapulgite and sepiolite as a control for the above experiments.
- 2) Redissolve all the Riley travertine samples using EDTA alone to eliminate possible problems inherent in the acetic-acid procedure.
- 3) The clay-size fraction should be further sized and scanning-electron micrographs should be made of a fraction appropriate to detect acicular attapulgite and/or sepiolite.
- 4) A recent caliche from the Riley area should be analyzed for attapulgite and sepiolite to see if they are forming under present conditions. This could include secondary carbonate material from case-hardened portions of the

Riley travertine.

- 5) Drill cores of the Riley travertine are in hand, and deeper portions should be analyzed as described earlier to eliminate any overprint in clay mineralogy from collecting near-surface samples.
- 6) Undertake additional detailed geology including dating, mapping (geologic and facies), thin-section analysis, and detailed sampling.

Acknowledgments

All the ideas expressed and the conclusions reached in this report are my own. My colleagues at the New Mexico Bureau of Mines and Mineral Resources were a great help in various portions of this study. In particular, I thank G. S. Austin, J. Renault, J. Love, R. M. North, K. B. Faris, and P. Cooksey for their time and contributions. Technical assistance was supplied by M. Bowie, B. Casselberry, and J. Hintgen.
