

# **Questa Rock Pile Weathering and Stability Project**

## **LITHOLOGIC ATLAS FOR THE QUESTA MINE, TAOS COUNTY, NEW MEXICO**

Virginia T. McLemore, Dawn Sweeney, and Kelly Donahue

May 21, 2009

New Mexico Bureau of Geology and Mineral Resources

Open-file Report OF-516

Molycorp Task 1.2.2, B1.1

**New Mexico Tech**

## EXECUTIVE SUMMARY

This report is one of a series of reports describing the effects of weathering on the long-term slope stability of the Questa rock piles. Descriptions of samples need to be consistent within this study as well as be consistent with other work being conducted by Chevron Mining, Inc. Thus, the purposes of this lithologic atlas are to:

- Familiarize workers with the lithologies that are most likely to appear in the Questa rock piles (i.e. the rocks that were mined from the open pit).
- Provide descriptions and photographs of these lithologies.
- Utilize the symbols that Chevron Mining, Inc. has identified as appropriate for naming the lithologies.
- Describe the alteration assemblages.
- Characterize the geochemistry of these altered lithologies.

This report includes descriptions and photographs of hand samples and thin sections of the different lithologies and alteration assemblages. Lithologies examined include andesite, quartz latite, rhyolite tuff (Amalia Tuff), aplite, granitic porphyry, miscellaneous dike, flows, volcanoclastic and tuffaceous rocks. Seven general types of hydrothermal alteration assemblages are found in the Red River-Rio Hondo and Questa districts and are found in the rock piles:

- Early and late propylitic (consisting of chlorite, calcite, pyrite, albite, epidote)
- Argillic and advanced argillic (consisting of chlorite, smectite, kaolinite, calcite, epidote, quartz, pyrite, clay minerals)
- Potassic (consisting of replacement of primary minerals by K-feldspar and potassium-bearing micas, illite, and sericite along with fluorite, quartz, and molybdenite)
- Quartz-sericite-pyrite (QSP), also is called phyllic, sericitic and silicic
- Magnetite veining
- Silicification (replacement by fine-grained quartz)
- Post-mineral carbonate-fluorite (locally with anhydrite)

Summary of current knowledge of composition of the overburden that went in the Questa rock piles:

- Chemically, the volcanic rocks in the Questa-Red River area are calc-alkaline, metaluminous to peraluminous igneous rocks.
- The rhyolite (Amalia Tuff) has more quartz and little to no epidote and chlorite compared to the andesite.
- The rhyolite (Amalia Tuff) typically has higher SiO<sub>2</sub>, K<sub>2</sub>O, Rb, Nb, less TiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>T, MgO, CaO, P<sub>2</sub>O<sub>5</sub>, and Sr than the andesite.
- Little, if any, unaltered rocks (i.e. primary magmatic) went into the Questa rock piles.
- The rock pile samples are a mixture of two or more rock types that were variably hydrothermally altered. GHN is a mixture of rhyolite (Amalia Tuff) and andesite.
- The rocks that went into the Questa rock piles were hydrothermally altered before mining, which resulted in large variations in mineralogical and chemical composition.
  - Amphiboles, pyroxenes, and feldspars were replaced by biotite and albite during alteration.

- Biotite, hornblende, pyroxenes were hydrothermally altered to chlorite, sericite, smectite, illite, and mixed layer clays (prophyllitic alteration).
- Feldspars show varying degrees of hydrothermal alteration to illite, kaolinite, smectite, quartz, mixed layer clays (QSP overprinting prophyllitic alteration).
- Many rocks were silicified, and this silicification was accompanied by the addition of 1-2 stages of pyrite, illite, calcite, and/or gypsum.

## **INTRODUCTION**

### **Purpose**

The Chevron Mining Inc. (formerly Molycorp, Inc.) Questa molybdenum mine is located on the western slope of the Taos Range of the Sangre de Cristo Mountains of the Southern Rocky Mountains near the edge of the Rio Grande rift in north-central New Mexico. The mine is on southward facing slopes and is bounded on the south by Red River (elevation of approximately 7500 ft) and on the north by the mountain divides (elevation approximately 10,750 ft). During the period of open-pit mining (1969-1982) at the Questa mine, approximately 350 million tons of overburden rock was removed and deposited onto mountain slopes and into tributary valleys forming nine rock piles surrounding the open pit. These are some of the highest rock piles in the United States. Since the rock piles were emplaced, a number of shallow-seated failures, or slumps, have occurred at Questa and a foundation failure occurred at Goathill North rock pile that resulted in sliding of the rock pile (Norwest Corporation, 2004). The purpose of the Questa Rock Pile Weathering and Stability Project (QRPWASP) is to determine what changes will occur in the rock piles over long periods of time (100 and 1000 years) due to weathering (both physical and chemical changes) and the effect of these changes on overall rock-pile stability.

This report is one of a series of reports describing the effects of weathering on the long-term slope stability of the Questa rock piles. Descriptions of samples need to be consistent within this study as well as be consistent with other work being conducted by Chevron Mining, Inc. Thus, the purposes of this lithologic atlas are to:

- Familiarize workers with the lithologies that are most likely to appear in the Questa rock piles (i.e. the rocks that were mined from the open pit).
- Provide descriptions and photographs of these lithologies.
- Describe the alteration assemblages.
- Characterize the geochemistry of these altered lithologies.

This report includes descriptions and photographs of hand samples and thin sections of the different lithologies and alteration assemblages. Note that scales of the photographs are in centimeters. Higher resolution photographs are available as part of the project database. The photographs are labeled by their sample numbers and location data can be found in the project database. Characterization of the alteration scar areas are in a separate report (Graf, 2008).

### **Acknowledgements**

This project was funded by Chevron Mining, Inc. (formerly Molycorp, Inc.) and the New Mexico Bureau of Geology and Mineral Resources (NMBGMR), a division of New Mexico Institute of Mining and Technology. We would like to thank the professional staff and students of the large multi-disciplinary field team for their assistance in mapping, sampling, and laboratory analyses. This report could not have been written without the years of work by Chevron Mining, Inc. geologists, especially Bruce Walker, and correlation efforts by Cori Hoag and her team from SRK and mapping by Mark Osterburg. Whole rock geochemical analysis was by Washington State University. Peter Lipman provided some of the chemical analyses used in this report. Nelia Dunbar, Bruce Walker, Solomon Ampim, Ariel Dickins and Jack Hamilton reviewed earlier versions of this report. This report is part of an on-going study of the

environmental effects of the mineral resources of New Mexico at NMBGMR, Peter Scholle, Director and State Geologist.

### **METHODS OF STUDY**

This study includes a review of the literature, field observations and sampling, and petrographic, mineralogical and chemical characterization of samples of various lithologies in the Questa-Red River area. Several different types of samples were collected:

- Outcrop samples of unweathered (or least weathered) igneous rocks representative of the mined rock (overburden) (includes all predominant lithologies and alteration assemblages at various hydrothermal alteration and weathering intensities)
  - andesite
  - quartz latite
  - rhyolite tuff (Amalia Tuff)
  - aplite, granitic porphyry
  - miscellaneous dike, flow, and tuffaceous rocks
  - alteration scars
- Samples of the vein material within altered host rocks (typically veins are <2 cm)
  - quartz-molybdenite-pyrite (orthoclase flooding, biotite)
  - quartz-sericite-pyrite of rhyolite porphyry dikes
  - quartz-fluorite-sericite-pyrite-base metal sulfides (halo above mineral deposits)
  - calcite-gypsum/anhydrite
- Weathering profiles of colluvium/weathered bedrock and alteration scars
- Sections of drill-core samples of the mined rock (overburden) and ore deposit before mining.

Different sampling strategies were employed based upon the purpose of each sampling task. Typically, at each site, a select, grab, or bulk sample of rock or soil material was collected for petrographic study and geochemical and geotechnical analyses. A hand specimen was collected from some sites for thin section analysis. The samples for this report consisted of grab samples of two or more pieces of outcrop or drill core samples (typically 3-8 cm in diameter). These samples are more homogeneous than rock-pile samples in that they are composed of one lithology and alteration assemblage, whereas the rock-pile material typically consists of multiple lithologies and/or alteration assemblages. A portion of the collected sample was crushed and pulverized for geochemical analysis. Thin sections were made of another piece of selected rock samples for petrographic analysis (including estimated modal mineralogical analysis). Some of the samples examined were obtained from the Chevron rock collection and only hand specimen descriptions of these rocks were performed. Additional mineralogical and chemical analyses of rock types were obtained from the literature and Peter Lipman (USGS). More detailed petrographic data are in the project database.

Samples were petrographically analyzed using a binocular microscope. Petrographic analysis included identification of minerals, lithologies and alteration types (propylitic, argillic, or quartz-sericite-pyrite (QSP) alteration). Propylitic alteration is

characterized by the presence of chlorite, epidote, calcite and pyrite. Argillic or clay alteration is characterized by the addition of clay minerals, especially chlorite and smectite. QSP alteration is characterized by the abundant presence of quartz and sericite (illite). Pyrite is found in both propylitic and QSP alteration types. Amalia Tuff was identified by the presence of fiamme (flattened pumice) and relatively small phenocryst size. Intrusive aplite samples were identified using crystalline textures, i.e. quartz in andesite and Amalia Tuff look different than quartz in intrusive aplite samples. Lithology and mineral abundances were visually estimated with standardized charts. Alteration intensity was also estimated.

Mineralogical data is obtained from several different techniques, including:

- Petrographic analysis of a bulk grab sub-sample using a binocular microscope (van der Plas and Tobi, 1965)
- Petrographic analysis of thin sections of the rock fragments using a petrographic microscope (including both transmitted- and reflected-light microscopy; van der Plas and Tobi, 1965; Delvigne, 1998)
- Electron microprobe analysis of both the fine-grained soil matrix and the rock fragments
- Clay mineral determination of a bulk sample split using clay separation techniques and X-ray diffraction analysis (Moore and Reynolds, 1989; Hall, 2004)
- Other methods of determining mineralogy (spectral analysis, X-ray diffraction, fizz test).

The bulk quantitative mineralogy was determined using a modified ModAn technique along with petrographic observations (including an estimated modal analysis), electron microprobe analysis, clay mineral analysis, and the whole-rock chemistry of the sample, as described by McLemore et al. (2009b). ModAn is a modeling program that uses whole-rock chemical and petrographic analyses to determine a normative quantitative mineralogy of the sample (Paktunc, 1999, 2001).

## **GEOLOGIC HISTORY**

The geology and mining history of the Questa-Red River area is complex, described by others (Carpenter, 1968; Clark, 1968; Reed et al., 1983; Lipman, 1988; Meyer and Leonardson, 1990; Czamanske et al., 1990; Roberts et al., 1990; Ludington et al., 2005), and summarized in McLemore (2009) and Table 1. Lithologies likewise are diverse, including granitic and gabbroic intrusive rocks and rhyolitic and andesitic volcanic rocks.

## **QUESTA ROCK PILES**

Approximately 135 million lbs of molybdenum were produced from the open-pit deposit (1969-1981) that resulted in approximately 350 million tons of overburden rock material deposited onto mountain slopes and into tributary valleys forming the nine rock piles and 50 million tons of tailings stored in the Guadalupe Mountain tailings facility at Questa (Fig.1). The current mine is an underground, molybdenum disulfide (“moly”) mine that uses a block-caving mining method to extract ore.

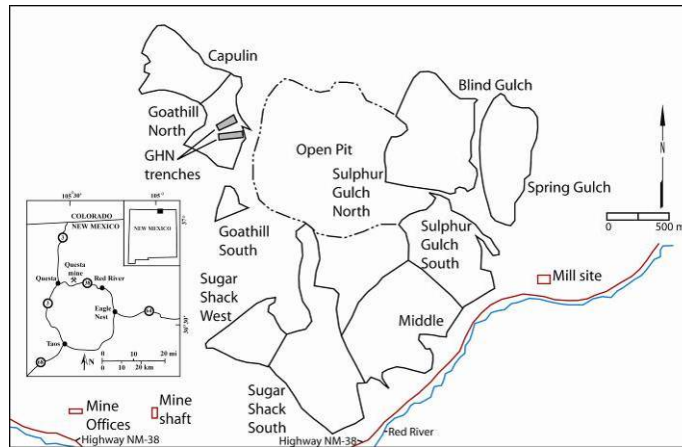

FIGURE 1. Location of the Questa rock piles and other mine features, including location of trenches constructed in Goathill North (GHN) rock pile.

TABLE 1. Summary of geologic history of the Questa area (Bauer et al., 2004; Ludington et al., 2005; Samuels, 2008; Zimmerer, 2008).

| Approximate age | Event   | Event   |
|-----------------|---|---|
| 2 Ma-present    | Pediment and stream deposits  |   |
| 4.5 Ma-present  | Beginning of alteration of scars  |   |
| 2.34-5.88 Ma    | Taos Plateau volcanic field   |   |
| 1-16.4 Ma       | Santa Fe Group  | Miocene lavas                                   |
| 5 Ma to present | Slow extension, basin subsidence  |   |
| 18.6-5 Ma       | Rapid extension of Rio Grande rift  |   |
| 16.5-22.9       | Postcaldera magmatism, southern margin  |   |
| 24.7-22 Ma      | Resurgent plutonism, postcaldera volcanism, southern caldera margin plutonism and Mo mineralization (Latir Peak volcanic field) | Slow extension of Rio Grande rift               |
| 25.2 Ma         | Amalia Tuff (Questa caldera collapse)   | peralkaline rhyolite dikes                      |
| 25.2-28.3 Ma    | Precaldera volcanism (Latir Peak volcanic field)  | sedimentary rocks                               |
| 28.5-33.7 Ma    | Early regional extension Rio Grande rift  | Transition from crustal shortening to extension |
| 33.7-65 Ma      | Laramide orogeny  |   |
| 1610-1752 Ma    | Precambrian rocks   |   |

The amount of the various lithologies that were mined from the open-pit deposit was calculated from Chevron data. The tailings or ore were not subtracted out. The procedure is summarized below:

1. Calculate areas for each lithology within the open pit as mapped on cross sections provided by SRK, using either rectangles or triangles.

2. Calculate a volume by multiplying each area by 200 ft (the distance between cross sections). This assumes that each lithology is a simple box.
3. Calculate total volume mined and divide each lithology to get a percentage of the lithology mined.

These estimated results are summarized by lithology in Table 2.

TABLE 2. Estimates of volume of each lithology mined from the open pit deposit. Description of the lithologies follows in the next section. The relative estimate of strength is based upon analyses of fractures and perceived integrity of the rock, which is dependent upon mineralogy (i.e. the more quartz in the rock, the stronger the rock, the more illite and chlorite, the weaker the rock). Symbols in parentheses are from Lipman and Reed (1989). QSP is quartz-sericite-pyrite hydrothermal alteration.

| Symbol                | Lithology  | Volume (percent) | Relative estimate of strength (1 strong, 3 weak) | Comments                          |
|-----------------------|--|------------------|--|-----------------------------------|
| Tdqpt-Trt (Trt, Trtl) | Amalia Tuff  | 10               | 1  | Mostly QSP altered, no ore        |
| Tanbx                 | Andesite breccia (includes latite, quartz latite and volcaniclastic rocks) | 14               | 3<br>2   | 50% QSP, 50% propylitic, no ore   |
| Tanfp (Ta)            | Fine-grained andesite (includes latite, quartz latite)                     | 46               | 3<br>2   | 50% QSP, 50% propylitic, some ore |
| Thfp                  | Christmas Tree porphyry  | 8                | 2  | QSP altered, no ore, pyrite rich  |
| Tpap (Tgy)            | Aplite (includes granite and rhyolite dikes)                               | 22               | 1  | Most of ore from this unit        |
| TOTAL                 |  | 100              |  |                                   |

Records were not kept detailing the construction of the rock piles. However, URS Corporation (2003) presents a summary of their construction as interpreted from dated air photographs. The development of the Questa open pit began with excavations along the west side of the pit and development continued progressively southeast along Sulphur Gulch. The top layers of the volcanic series, mainly the rhyolite (Amalia Tuff) and andesites (flows and porphyry units), located along the west side of the pit were mined first and placed in the rock piles. A portion of the large natural alteration scar (which has relatively high pyrite concentrations) located on the west and northwest side of the open pit (Questa Pit Scar in Sulphur Gulch) was mined early in the development of the open pit. Aplite and granite were mined from the lower portion of the open pit and the aplite overlies the black andesite. A wrap-around berm of aplite provided a shallow cover over the mixed volcanics unit over the lowest lift of the southern mine rock piles.

## DESCRIPTION OF ALTERATION

*Alteration* is a general term describing the changes in mineralogy, texture, and chemistry of a rock as a result of a change in the physical, thermal, and chemical environment in the presence of water, steam, or gas, including those changes produced by weathering (Henley and Ellis, 1983; Reed, 1997; Neuendorf et al., 2005; Ludington et al., 2005). The nature of the alteration depends upon (Browne, 1978; Henley and Ellis, 1983; Ludington et al., 2005):

- Temperature and pressure (including amount of overburden or depth) at the alteration site
- Composition of the parent rock
- Composition of the altering (invading) fluids
- Permeability of the parent rock
- Duration and intensity of the alteration process (i.e. time)
- Distance from the alteration source, resulting in alteration zoning.

Alteration includes hypogene or hydrothermal (primary), supergene (secondary), and weathering alteration. *Hypogene alteration* occurred below the surface during the formation of the ore body by upwelling (ascending), hydrothermal or warm to hot fluids (Neuendorf et al., 2005). *Supergene alteration* is the natural weathering, before mining, of the ore body, at low temperatures near the Earth's surface by descending fluids (Neuendorf et al., 2005). *Weathering* is the set of physical and chemical changes, up to and including disintegration of rock by physical, chemical, and/or biological processes occurring at or near the earth's surface (e.g., in the vadose zone within approximately 100 m of ground surface at temperatures less than or equal to approximately 70°C) that result in reductions of grain size, changes in cohesion or cementation, and change in mineralogical composition (modified from Neuendorf et al., 2005). General discussions of hydrothermal alteration associated with Climax-type porphyry molybdenum deposits are by Westra and Keith (1981), Mutschler et al. (1981), Ludington (1986), Carten et al. (1993), and Ludington et al. (1995, 2005). This report describes the hypogene (hydrothermal) and supergene alteration. The effects of weathering after being emplaced in the rock piles are described in McLemore et al. (2006a, b, 2008a, b).

The hydrothermal alteration at Questa is similar to most Climax-type porphyry molybdenum systems and exhibits a distinctive district alteration zoning (Fig. 2; Martineau et al., 1977; Loucks et al., 1977; Molling, 1989; Meyer and Leonardson, 1990; Ross et al., 2002; Ludington et al., 2005). The mined overburden material that went into the rock piles was mostly from the upper portions of the hydrothermally altered system. Seven general types of hydrothermal alteration assemblages are found in the Red River-Rio Hondo and Questa districts and are found in the rock piles (Fig. 2; Martineau et al., 1977; Molling, 1989; Meyer, 1991; Reed, 1997):

- Early and late propylitic (consisting of chlorite, calcite, pyrite, albite, epidote)
- Argillic and advanced argillic (consisting of chlorite, smectite, kaolinite, calcite, epidote, quartz, pyrite, clay minerals)
- Potassic (consisting of replacement of primary minerals by K-feldspar and potassium-bearing micas, illite, and sericite along with fluorite, quartz, and molybdenite)
- Quartz-sericite-pyrite (QSP), also is called phyllic, sericitic and silicic
- Magnetite veining
- Silicification (replacement by fine-grained quartz)
- Post-mineral carbonate-fluorite (locally with anhydrite).

The manner in which these alterations express themselves mineralogically and chemically depends on:

- The original rock types
- The paleo-hydrology that distributed the alteration solutions

- Subsequent geologic history
- Intensity of molybdenum mineralization.

Supergene alteration is commonly superimposed on the hypogene alteration, especially in near-surface rocks mined early in the history of Questa. In some places, supergene weathering along open fracture systems can extend to considerable depths. Weathering is superimposed on both the hypogene and supergene alteration.

Regional fracturing of the pre-mined rock occurred during igneous intrusion and hydrothermal alteration and formed jointed rocks with a few distinctive patterns such as orthogonal, oblique orthogonal, and conjugate joint sets (Caine, 2003, 2006; Ludington et al., 2005). Three types of fault zones are present and include partially silicified, low- and high-angle faults with well-developed damage zones and clay-rich cores and high-angle, unsilicified open faults (Caine, 2006). These faults and fractures not only provide pathways for modern fluids (Caine, 2006), but also provide for angular rock fragments when the material is blasted. These angular rock fragments when found in the rock pile provide for stronger material (McLemore et al., 2009a).

### **Propylitic alteration (chlorite, $\pm$ epidote)**

Propylitic alteration, in part, spatially overlaps and, in part, occurs peripherally to QSP alteration. It typically forms at low temperatures, 200-350°C (Reed, 1997). This mineral assemblage consists of essential chlorite (producing the green color), epidote, albite, pyrite, quartz, carbonate minerals, and a variety of additional minerals depending upon host-rock lithology, temperature, and composition of the fluids, including zeolites, adularia, sericite/illite, smectite, kaolinite, etc. Propylitically altered rocks are typically green to green-gray in color as a result of the presence of chlorite and epidote (Fig. 3). Hematitization producing a brown to red-brown color masking the green color also is common. Propylitic alteration occurred in two phases in the Questa-Red River area:

- Early stage, overlapping QSP alteration
- Late, district-wide stage followed by QSP alteration.

It is difficult to distinguish between these two stages (Ludington et al., 2005). Propylitic alteration is best developed in andesites, latites, volcanic breccias, and volcanoclastic rocks and less developed in the granitic porphyries and rhyolite (Amalia Tuff), because the granitic and rhyolitic rocks have less mafic minerals containing Ca, Mg, Mn, and Fe required to form chlorite and epidote.

The groundmass is replaced by quartz, calcite, smectite, kaolinite, and chlorite; feldspar phenocrysts are partially or completely replaced by quartz, chlorite, albite, and calcite. Episodic periods of alteration probably occurred as evidenced by overlapping veinlets and replacement textures. Thin veinlets of quartz-pyrite or calcite, less than a millimeter wide, cut across chloritized andesite, but are subsequently offset by younger veinlets of calcite. Epidote and chlorite locally replace plagioclase. Quartz-pyrite and pyrite veinlets are common along fractures within the andesite. Disseminated pyrite occurs in the andesite and pyrite locally replaces hornblende and olivine grains in the andesite. These different forms and occurrences of pyrite suggest several stages of pyrite occurred.

### Argillic alteration

Argillic or clay alteration consists of kaolinite, smectite (montmorillonite clays), chlorite, epidote, and sericite and overlaps the other types of hydrothermal alteration. Chlorite has replaced mafic minerals and the groundmass within the andesite. Disseminated pyrite is locally pervasive in the andesite. Locally, chlorite and epidote veinlets formed along fractures. Calcite occurs as thin veins and also replaces feldspar crystals. Sericite also replaces K-feldspar phenocrysts (Fig. 4). Advanced argillic alteration consists of kaolinite, quartz, alunite, jarosite, pyrophyllite, and other aluminosilicate minerals and is found in the alteration scars and along some faults in the mine area. Argillic alteration is best developed in andesites, latites, volcanic breccias, and volcanoclastic rocks, but is common in the granitic porphyries and rhyolite (Amalia Tuff), because the available minerals can alter to clay minerals during hydrothermal alteration.

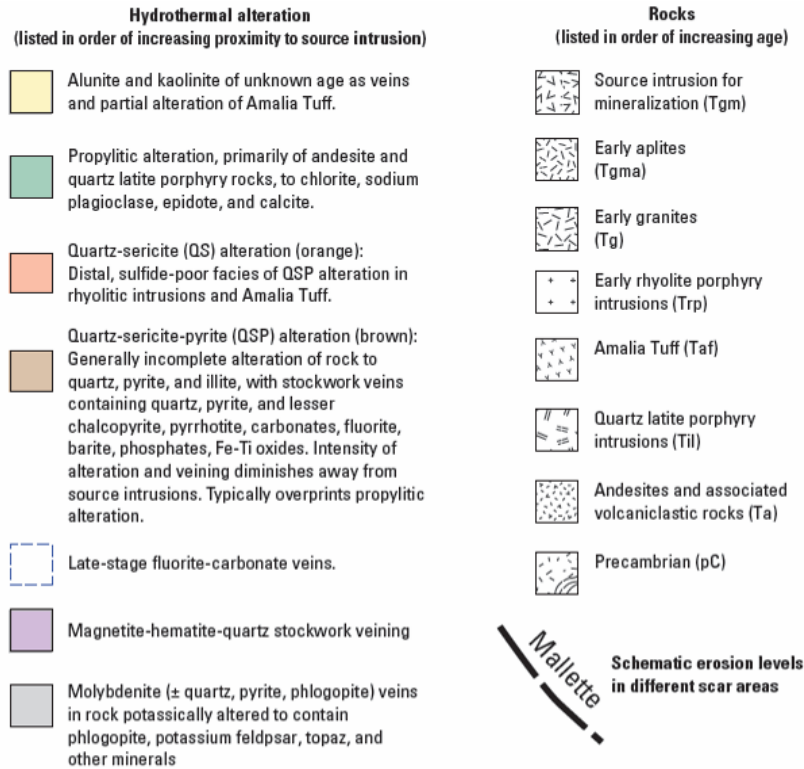

FIGURE 2. Cross section showing schematic spatial distributions of lithologies, alteration assemblages, and alteration scars in the Red River valley (taken from Ludington et al., 2005, which is modified from Martineau et al., 1977).

FIGURE 3. Propylitic alteration as indicated by green chlorite (chl) and brown feldspar (kspar) minerals in sample GMG-PIT-0013 in plane polarized light; field of view is approximately 1.8 mm.

FIGURE 4. Backscattered electron microprobe image showing argillic alteration where clay minerals replacing feldspar phenocrysts (kspar) in sample PIT-KMD-0007.

### Potassic alteration

Potassic alteration is typically the predominant type of hydrothermal alteration in the Questa area, but is not as predominant in the rock piles because it is directly associated with the molybdenum mineralization and these rocks went to the mill for processing. Potassic alteration at Questa, like most Climax-type deposits is characterized by the addition of potassium as secondary hydrothermal biotite, K-feldspar, and sericite along with quartz, fluorite, molybdenite, and pyrite as disseminations, veinlets and large crystals replacing the host rocks. Sericite includes the minerals illite, sericite, and/or muscovite. The major difference between these three K-micas is size: illite is a clay-size K-mica, whereas muscovite is larger. Sericite is of intermediate size. Some minor

compositional differences, especially in potassium content, also occur between the three minerals. Characteristic textures include large K-feldspar crystals and rimming of plagioclase by K-feldspar. Potassic alteration is one of the most pervasive alteration types in the Questa area and found in all rock types (Ludington et al., 2005). Stockwork magnetite-hematite veins with intergrown anhydrite/gypsum overlaps the potassic alteration along the edges of some veins (Martineau et al., 1977).

#### **Phyllic or QSP alteration (Quartz-sericite-pyrite)**

Phyllic or QSP (quartz-sericite-pyrite) alteration is widespread above the Questa molybdenum deposit, is typically above or overlaps the potassic alteration (Fig. 2), and is common within the rock piles and various lithologies in the Questa area. QSP alteration is defined by the predominance of quartz, sericite, and pyrite. QSP alteration typically is found as thin QSP veinlets cutting the host rock and as quartz, sericite, and pyrite replacing the groundmass and primary igneous minerals (Fig. 5, 6). The proportions of quartz, sericite, and pyrite vary according to the intensity of alteration. Typically quartz exceeds sericite, which exceeds pyrite in abundance. The amount of pyrite typically decreases away from the ore body. QSP alteration is commonly crosscut by intersecting stockwork veins, up to a few centimeters wide and consisting of quartz, pyrite, sericite, and rarely chalcopyrite, sphalerite, and galena.

FIGURE 5. Sample PIT-LFG-0001 shows moderate QSP alteration under crossed polarized light; field of view is approximately 1.8 mm. The feldspar phenocryst (kspar) is well-defined and the groundmass is replaced by quartz and sericite.

#### **Silicification**

Silicification is produced by the addition of silica, predominantly as quartz. Quartz occurs as amygdale-fillings, fracture coatings, thin quartz veins, breccia cements, and as replacements of primary minerals. Silicification differs from the QSP alteration in that only replacement of quartz occurred without pyrite and sericite and is typically restricted to halos surrounding veins and within fault zones.

FIGURE 6. Sample PIT-KMD-0007 showing moderate to strong QSP alteration. The feldspar (kspar) phenocryst are replaced by quartz and sericite and the grain boundaries are poorly defined both in plain polarized light and under crossed polarized light; field of view is approximately 1.8 mm.

### Carbonate-fluorite and magnetite-hematite veins

Intersecting veins of predominantly carbonate (manganiferous calcite, dolomite, rhodochrosite), anhydrite/gypsum, fluorite, and magnetite or hematite crosscut the molybdenum veins and potassic and QSP altered rocks near the ore body and within the alteration scars. Locally sericite/illite is found in some of these veins.

## MINERALOGY

Petrographic and microprobe studies and review of the literature have identified the minerals in the Questa mine rock piles and probable elemental composition of these minerals, summarized in Table 3.

TABLE 3. Relative stabilities, approximate concentrations, and compositions of minerals found in Questa rock pile deposits (NM Tech electron microprobe results in bold, other elements by Molling, 1989; Shum, 1999; Piché and Jébrak, 2004; Plumlee et al., 2005). Tr=trace, Approx=approximate concentration in the Questa rock-pile materials

| Relative stability | Mineral            | Approx % | Primary elements   | Trace elements                           | Formula   |
|--------------------|--------------------|----------|--------------------|--|---|
| Easily weathered   | pyrite             | 0-8      | <b>Fe, S</b>       | <b>Cu, Te, Co, Pb</b>                    | FeS <sub>2</sub>  |

### Clay mineralogy

Several outcrop and drill core samples were examined for their clay mineralogy by using X-ray diffraction (XRD) techniques to identify the clay minerals present in the Questa rock materials (Fig. 7). Different lithologies and hydrothermal-alteration assemblages were chosen. The host-rock lithology is one of the main factors controlling the clay mineral assemblages due to the presence or absence of certain primary minerals, such as amphiboles and micas. For example, high abundances of chlorite are found almost exclusively in andesitic rock types (Fig 7a). However, the results of the XRD analyses indicate another controlling factor in the clay mineral assemblage is the type of hydrothermal alteration. The QSP-altered samples of andesite and rhyolite composition result in similar mineral assemblages of predominantly illite and minor kaolinite (Fig. 7b). Over-printing of alteration mineral assemblages results in samples containing each of the clay-mineral groups (illite, kaolinite, chlorite, smectites, mixed layered clays) despite

a difference in host rock lithology (Fig. 7c). The drill-core samples collected near the center of the ore deposit have more than one type of over-printing hydrothermal alteration mineral assemblage due to the nature of the ore deposit.

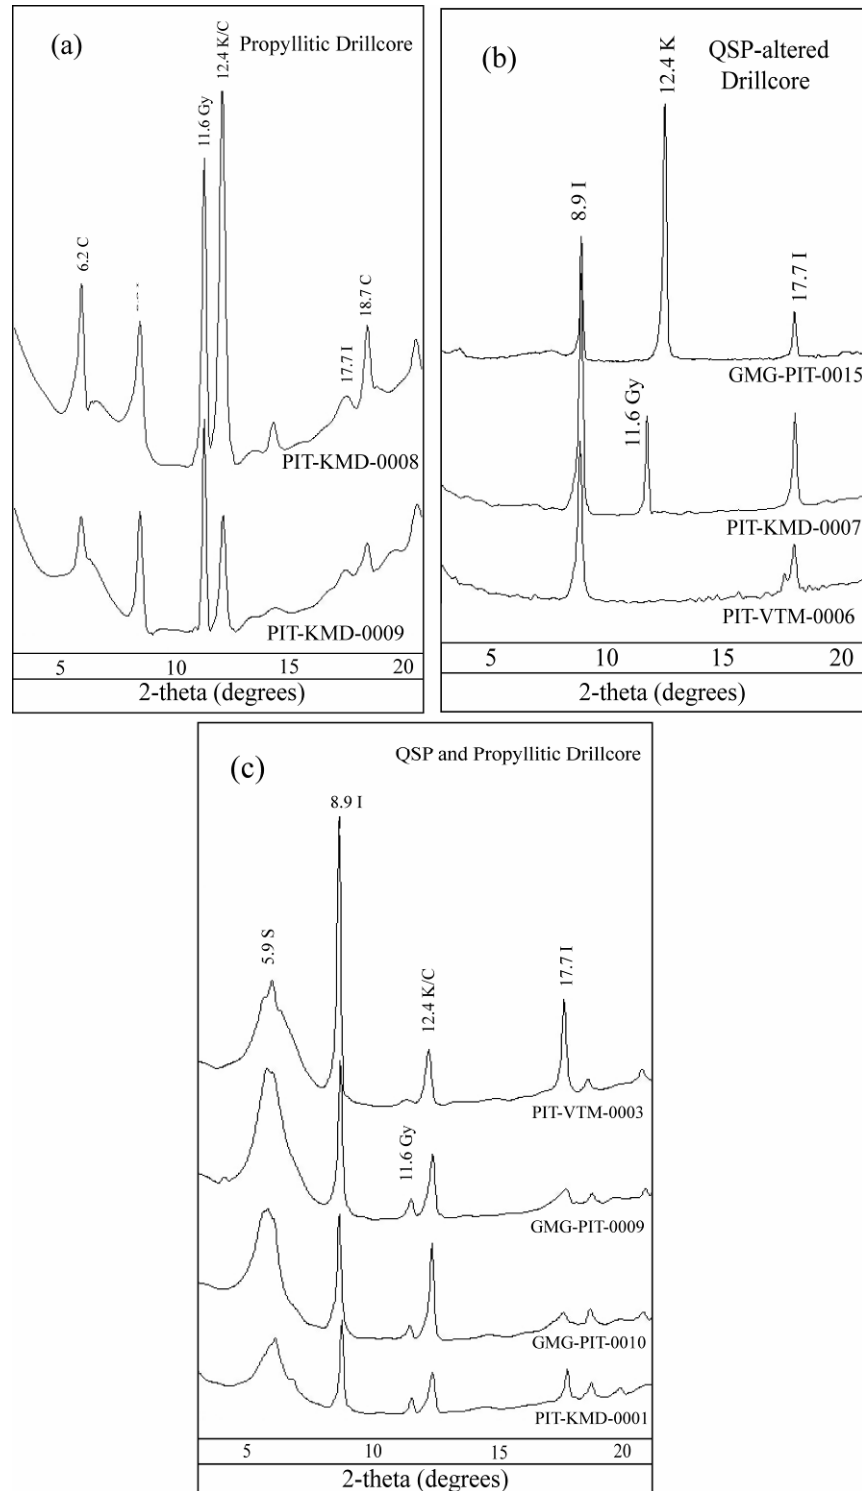

FIGURE 7. a) The XRD results of drill-core clay analyses of propylitically altered andesite samples, b) the XRD results of andesite and rhyolite QSP-altered core samples

and c) andesite and rhyolite drill core samples with evidence of over-printing hydrothermal alteration assemblages. I = illite, K = kaolinite, C = chlorite, S = smectite, Gy = gypsum.

## **LITHOLOGIC DESCRIPTIONS**

### **Felsic Intrusions**

#### **Goathill Porphyry**

The Goathill Porphyry (Table 4) is a major intrusion that forms Goat Hill, west of the rock piles and the pit (Figs. 8, 9). Numerous dikes of the Goathill Porphyry cut the overburden and the open-pit deposit. This porphyry was intruded after or during the molybdenite mineralization. It is characterized by an aphanitic groundmass with 15-20% phenocrysts that consist of quartz (large crystals >5mm), plagioclase, orthoclase, and minor mafic minerals, but hornblende is absent. The large quartz phenocrysts are typically round or oval; whereas the feldspars are large blocky, cream-colored phenocrysts. A rare rapakivi texture can be present where the K-feldspars are rimmed with plagioclase. Some company and other descriptions refer to a quartz-feldspar porphyry that is now considered to be equivalent to the Goathill Porphyry.

FIGURE 8. Sample ROC-VTM-G005 showing typical propylitic texture of the cream-colored Goathill Porphyry.

FIGURE 9. Sample ROC-VTM-G011 is QSP-altered Goathill Porphyry. Note the holes caused by loss of quartz phenocrysts. This rock in a weathered state would be stained yellow.

TABLE 4. Summary descriptions of felsic intrusions. Sample locations are given in the UTM column (zone 13). na indicates the UTM coordinates are not available for the sample (samples are from the Chevron rock collection).

### Christmas Tree porphyry or Hornblende feldspar porphyry

The hornblende feldspar porphyry (Table 4) is the major porphyritic intrusion in the open-pit area, especially along strike of the NE zone and is locally referred to as the Christmas Tree porphyry (Fig. 10-15). It has a cream-colored aphanitic groundmass that is a phenocryst-rich porphyry with abundant broken crystals of black, tabular to blocky to square hornblende; clear, round to oval quartz; and large, cream, blocky feldspar phenocrysts. Characteristically the phenocrysts consist of 6-10% (2-5 mm) anhedral (often vermicular) quartz, 20-25% (2-20 mm) subhedral orthoclase, 6-8% (3-8 mm) subhedral plagioclase, 4-6% (1-4 mm) subhedral biotite, 2-5% (2-8 mm) euhedral hornblende, and as much as 1-3% magnetite. There are two compositions depending upon the quartz concentration: rhyolite and quartz latite. Pyrite (3-5%) is common as disseminations, thin fracture-fillings, and along phenocrysts boundaries. Rimmed feldspars are locally common. The Christmas Tree porphyry can include large blocks of andesite and rhyolite (Amalia Tuff) as a megabreccia.

FIGURE 10. (A) Sample ROC-VTM-G007 is coarse-grained, cream-colored, phenocryst-rich Christmas Tree Porphyry (Thfp) with black hornblende, clear quartz, and cream feldspar phenocrysts. (B) Sample PIT-KMD-0001 showing hand sample of cream-colored, porphyritic, Christmas Tree Porphyry.

FIGURE 11. Thin section of sample PIT-KMD-0001 showing Christmas Tree porphyry, consisting of quartz, feldspar, calcite, clays and trace amounts of pyrite, magnetite and biotite. Magnification is 5 times and field of view is 1.8 mm.

FIGURE 12. Sample ROC-VTM-G008 is coarse-grained, cream-colored, phenocryst-rich Christmas Tree porphyry intruded by a small cream-colored aplite dike.

FIGURE 13. (A) Sample ROC-VTM-G027 is QSP-altered aplite porphyry with trace of pyrite. (B) Sample PIT-VCV-0028 is QSP-altered aplite porphyry with fresh disseminated pyrite.

FIGURE 14. Thin section photographs of sample PIT-VCV-0028 showing QSP-altered aplite, under plane polarized light (A) and with crossed polarized light (B), 5 times magnification and a field of view of approximately 1.8 mm. Illite has replaced the feldspar phenocryst.

FIGURE 15. Sample ROC-VTM-G026 is fine-grained (aplitic) phase of the QSP-altered Christmas Tree porphyry consisting of very small quartz, feldspar, and hornblende phenocrysts and 5% disseminated pyrite.

### Plagioclase (biotite) aplite porphyry

The primary granitic porphyry in the open pit is the plagioclase aplite porphyry (Table 4), which is an allotriomorphic, granular aplitic groundmass of quartz, orthoclase, plagioclase and minor mafic minerals with 0-2% (2-5 mm) anhedral quartz, 3-6% (2-7 mm) subhedral orthoclase, 4-8% (2-10 mm) subhedral biotite, and trace hornblende (Figs. 16-17). It appears to grade into finer-grained allotriomorphic granites at depth, with a fine-grained aplitic matrix containing abundant minute (0.25-1 mm) crystals of quartz and orthoclase with 2-6% (2-6 mm) anhedral quartz, 2-5% (1-3 mm) subhedral orthoclase, 4-8% (2-6 mm) subhedral plagioclase, 3-6% (0.5-4 mm) euhedral hornblende. The Near Aplite (fine sub-aplitic matrix of quartz, orthoclase, plagioclase, and abundant fine biotite) occurs along contact of aplite just beneath other volcanic rocks and is interpreted to represent a hybrid derived by assimilation of andesite as aplite intrusions intruded into the volcanic pile.

FIGURE 16. (A) Sample ROC-VTM-G010 is pink, plagioclase aplite porphyry to porphyritic aplite with quartz, feldspar, and biotite phenocrysts. (B) Sample ROC-MZQ-0006 is peach-colored, fine-grained, plagioclase aplite.

FIGURE 17. Thin section photograph of sample ROC-MZQ-0006 showing aplite with quartz, feldspar and some biotite under normal polarized light (A) and crossed polarized light (B). Magnification is 5 times and field of view is 1.8 mm.

### Granite porphyry

The granite porphyry is a porphyritic intrusion with a phaneritic matrix, coarse allotriomorphic to hypidiomorphic textures, and consists of 30% (0.5-2 mm) quartz, 35% (0.5-3 mm) orthoclase, 20% (0.5-3 mm) plagioclase, 1% (0.25-2 mm) subhedral biotite (Figs. 18-19). The phenocrysts include 8-10% (3-10 mm) anhedral to subhedral quartz and 4-6% (3-12 mm) subhedral orthoclase.

FIGURE 18. (A) Sample ROC-VTM-G012 is granite porphyry from the underground deposit. (B) Sample PIT-VCV-0016 is granite porphyry with pink feldspars, quartz, and greenish-black micas.

FIGURE 19. Thin section photos of sample PIT-VCV-0016 under normal polarized light (A) and crossed polarized light (B) with quartz, feldspars, and micas, 5 times magnification and field of view of approximately 1.8 mm.

### Amalia Tuff

The Amalia Tuff is a welded, gray to reddish brown rhyolite ignimbrite (ash flow tuff) that typically contains 10-20% phenocrysts of alkali feldspar (albite-orthoclase) and quartz with sparse ferrohedenbergite, fayolite, and sodic amphibole (Figs. 20-32). The eutaxitic texture or flow banding produced by flattened pumice fragments is characteristic of the Amalia Tuff. Pumice is common in fresh samples and typically characterizes the foliation or flow banding. Quartz typically is found as round to oval phenocrysts that are typically persistent even in highly altered and weathered rock. Some confusion has existed in the literature and company descriptions as to the extent and correlations of the Amalia Tuff. It is now believed that what was called the Pit Porphyry and Capulin Quartz

Porphyry are not intrusions, but ash flow tuffs belonging to the Amalia Tuff. At the base of the Amalia Tuff, fragmental tuff and mudflow units are found locally. These units are a component within the open-pit deposit and overburden and are found in the rock piles. Sample descriptions for the QRPWASP should include the appropriate symbols as listed in Table 5.

TABLE 5. Summary descriptions of Amalia Tuff. na indicates the UTM coordinates are not available for the sample.

### **Latir Volcanic Rocks**

The Latir volcanic rocks consist primarily of andesite, latite, dacite, and quartz latite lava flows with interbedded mudflows, sandstones, and breccias (Table 6).

### Coarse-grained porphyritic andesite

The coarse-grained porphyritic andesite contains as much as 30% (5 mm) euhedral plagioclase, 1-8% (1-5 mm) euhedral biotite, 1-10% (2-8 mm) euhedral hornblende, and 0-5% (1-3 mm) subhedral quartz (Figs. 33-36). It is found as extensive flows up to 200 ft thick.

FIGURE 33. (A) Sample ROC-VTM-G015 is relatively fresh andesite of the Latir volcanics sequence. (B) Sample PIT-KMD-0009 is porphyritic andesite with some propylitic alteration.

FIGURE 34. Thin section photographs of sample PIT-KMD-0009, andesite under normal plane polarized light (A) and crossed polarized light (B) showing propylitically-altered feldspars (cream colored) and chlorite (green) minerals. Feldspars show replacement by illite (brown). Magnification is 5 times and field of view is approximately 1.8 mm.

### **Fine-grained porphyritic andesite**

The fine-grained porphyritic andesite contains as much as 30% (5 mm) euhedral plagioclase, 1-8% (1-5 mm) euhedral biotite, 1-10% (2-8 mm) euhedral hornblende, and 0-5% (1-3 mm) subhedral quartz (Figs. 37-42). It is found as extensive flows up to 200 ft thick and as minor dikes and sills.

FIGURE 37. Sample ROC-VTM-G016 is light gray porphyritic, crystal-rich andesite of the Latir volcanics with feldspar, biotite, and hornblende phenocrysts.

FIGURE 38. (A) Sample ROC-VTM-G021 is greenish gray, finely porphyritic andesite of the Latir volcanics with epidote alteration. (B) Sample PIT-VCV-0009 is propylitically-altered porphyritic andesite with disseminated pyrite.

FIGURE 39. Thin section of sample PIT-VCV-0009, andesite, under normal plane polarized light (A) and crossed polarized light (B) showing quartz, feldspar, and pyrite grains in a fine-grained groundmass. Magnification is 5 times and field of view is approximately 1.8 mm.

FIGURE 40. (A) Sample ROC-VTM-G025 shows a vein of quartz-pyrite-sericite (QSP alteration) cutting andesite of the Latir volcanics. (B) Sample PIT-KMD-0007 is QSP-

hydrothermally-altered andesite with finely disseminated pyrite and quartz-molybdenum-pyrite veining.

FIGURE 41. Thin section photographs of sample PIT-KMD-0007, andesite, under normal plane polarized light (A) and crossed polarized light (B) showing highly altered feldspar phenocrysts replaced by illite and with chlorite (green) and other clay minerals. Magnification is 5 times and field of view is approximately 1.8 mm.

### **Fine-grained andesite**

The fine-grained andesite contains as much as 30% (5 mm) euhedral plagioclase, 1-8% (1-5 mm) euhedral biotite, 1-10% (2-8 mm) euhedral hornblende, and 0-5% (1-3 mm) subhedral quartz (Figs. 42). It is found as extensive flows up to 200 ft thick and as minor dikes and sills.

FIGURE 42. Sample ROC-VTM-G023 is greenish-gray, propylitic-altered, fine-grained andesite of the Latir volcanics. Pyrite-filled fractures cut the andesite.

### **Quartz latite**

The quartz latite is porphyritic to fine grained and contains as much as 25% (5 mm) euhedral plagioclase, 1-8% (1-5 mm) euhedral biotite, 1-10% (2-8 mm) euhedral hornblende, and 5-10% (1-3 mm) subhedral quartz (Figs. 43-44). It is found as extensive flows up to 200 ft thick and as minor dikes and sills.

FIGURE 43. (A) Sample ROC-VTM-G013 is gray quartz latite flow of the Latir volcanics with feldspar, quartz, hornblende phenocrysts. (B) Sample GMG-PIT-0009 is white-gray hydrothermal-altered quartz latite porphyry with pink and white feldspar phenocrysts.

FIGURE 44. Thin section photographs of sample GMG-PIT-0009, andesite, under normal plane polarized light (A) and crossed polarized light (B) showing quartz and feldspar phenocrysts with a hydrothermally altered mica grain, now chlorite, in a fine-grained hydrothermally altered groundmass. Magnification is 5 times and field of view is approximately 1.8 mm.

#### **Fine-grained, porphyritic andesite**

The fine-grained, porphyritic andesite consists of 50-70% (0.5-2 mm) subhedral plagioclase laths (Fig. 45-46).

FIGURE 45. Sample ROC-VTM-G022 is fine-grained, porphyritic andesite of the Latir volcanics. Porphyritic texture with small phenocrysts of feldspar and disseminated pyrite.

FIGURE 46. Sample ROC-VTM-G031 is fine-grained, porphyritic andesite of the Latir volcanics showing phyllic alteration overprinted by QSP alteration.

### **Biotitized andesite**

One stage of the hydrothermal alteration produces biotite in the altered andesite and is shown in Figure 47.

FIGURE 47. Sample ROC-VTM-G014 is fine-grained black andesite of the Latir volcanics containing pyrite and showing biotitization.

### Andesite breccia

Andesite flow breccias include poorly-sorted andesite fragments of all types of andesite in fragmental, purple to gray to green matrix (Fig. 48-51). Matrix contains sparse fragmental quartz crystals and can be latitic in composition. It forms as upper units of the andesitic volcanic sequence, and is locally interbedded with rhyolite flows. It is typically greenish gray due to epidote and chlorite alteration and is locally called watermelon breccia.

FIGURE 48. (A) Sample ROC-VTM-G029 is andesite breccia of the Latir volcanics, locally called watermelon breccia. (B) Sample MIN-VTM-0001 is hand sample of watermelon breccia.

FIGURE 49. Thin section photographs of sample MIN-VTM-0001, andesite, under normal plane polarized light (A) and crossed polarized light (B) showing chlorite (green to brown) and altered feldspars replaced by illite (cream colored). Magnification is 5 times and field of view is approximately 1.8 mm.

FIGURE 50. Sample ROC-VTM-G028 is andesite breccia of the Latir volcanics.

FIGURE 51. Sample ROC-VTM-G024 is greenish-gray to purplish-gray andesite breccia of the Latir volcanics with propylitic alteration. Pyrite mineralized clasts are outlined.

### **Volcaniclastic rocks**

Minor sandstones, siltstone, shales, and volcanic breccias are interbedded with the andesite and latite flows of the Latir volcanics (Figs. 52-53). These volcaniclastic rocks, if hydrothermally altered, are difficult to distinguish from altered andesite and latite flows.

FIGURE 52. Photograph of sample GHR-VWL-0006-T002 is a hydrothermally altered, matrix-supported sandstone.

FIGURE 53. Photograph of sample GHR-VWL-00011-T002 is a hydrothermally altered, fine-grained sandstone.

### CHEMICAL CHARACTERIZATION OF THE LITHOLOGIES AND ALTERATION ASSEMBLAGES AT QUESTA

The average range in mineralogical compositions of relatively unaltered lithologies in the Questa-Red River area are listed in Table 7, obtained from petrographic analysis performed in this study and from published literature (Lipman and Read, 1989; Molling, 1989; Meyer, 1991). The average whole-rock chemical compositions of relatively unweathered volcanic and intrusive rocks (including various hydrothermally-altered rocks) in the Questa-Red River area are listed in Table 8, obtained from published literature and this project (Lipman and Read, 1989; Molling, 1989; Meyer, 1991). Mineralogical and chemical compositions of relatively unweathered volcanic and intrusive rocks (including various hydrothermally-altered rocks) in the Questa-Red River area are in Appendix 1.

Chemically, the volcanic rocks in the Questa-Red River area are calc-alkaline, metaluminous to peraluminous igneous rocks (Fig. 54). In general, the volcanic rocks plot in appropriate fields identified as andesite, rhyodacite, and rhyolite on typical litho-geochemical classification diagrams (Fig. 55). The rhyolite (Amalia Tuff) has more quartz and little to no epidote and chlorite compared to the andesite. The rhyolite typically has higher  $\text{SiO}_2$ ,  $\text{K}_2\text{O}$ ,  $\text{Rb}$ ,  $\text{Nb}$ , less  $\text{TiO}_2$ ,  $\text{Al}_2\text{O}_3$ ,  $\text{Fe}_2\text{O}_3\text{T}$ ,  $\text{MgO}$ ,  $\text{CaO}$ ,  $\text{P}_2\text{O}_5$ , and  $\text{Sr}$  than the andesite.

TABLE 7. Average range in modal mineralogical compositions in weight percent of relatively unweathered major volcanic and intrusive rocks at the Questa mine (Lipman and Read, 1989; Molling, 1989; Meyer, 1991; and petrographic analyses by E.H. Phillips, D. Sweeney, V.T. McLemore). Tr=trace

|             | Andesite (%) | Quartz Latite (%) | Amalia Tuff (rhyolite) (%) | Goathill Porphyry (%) | Aplite porphyry (%) |

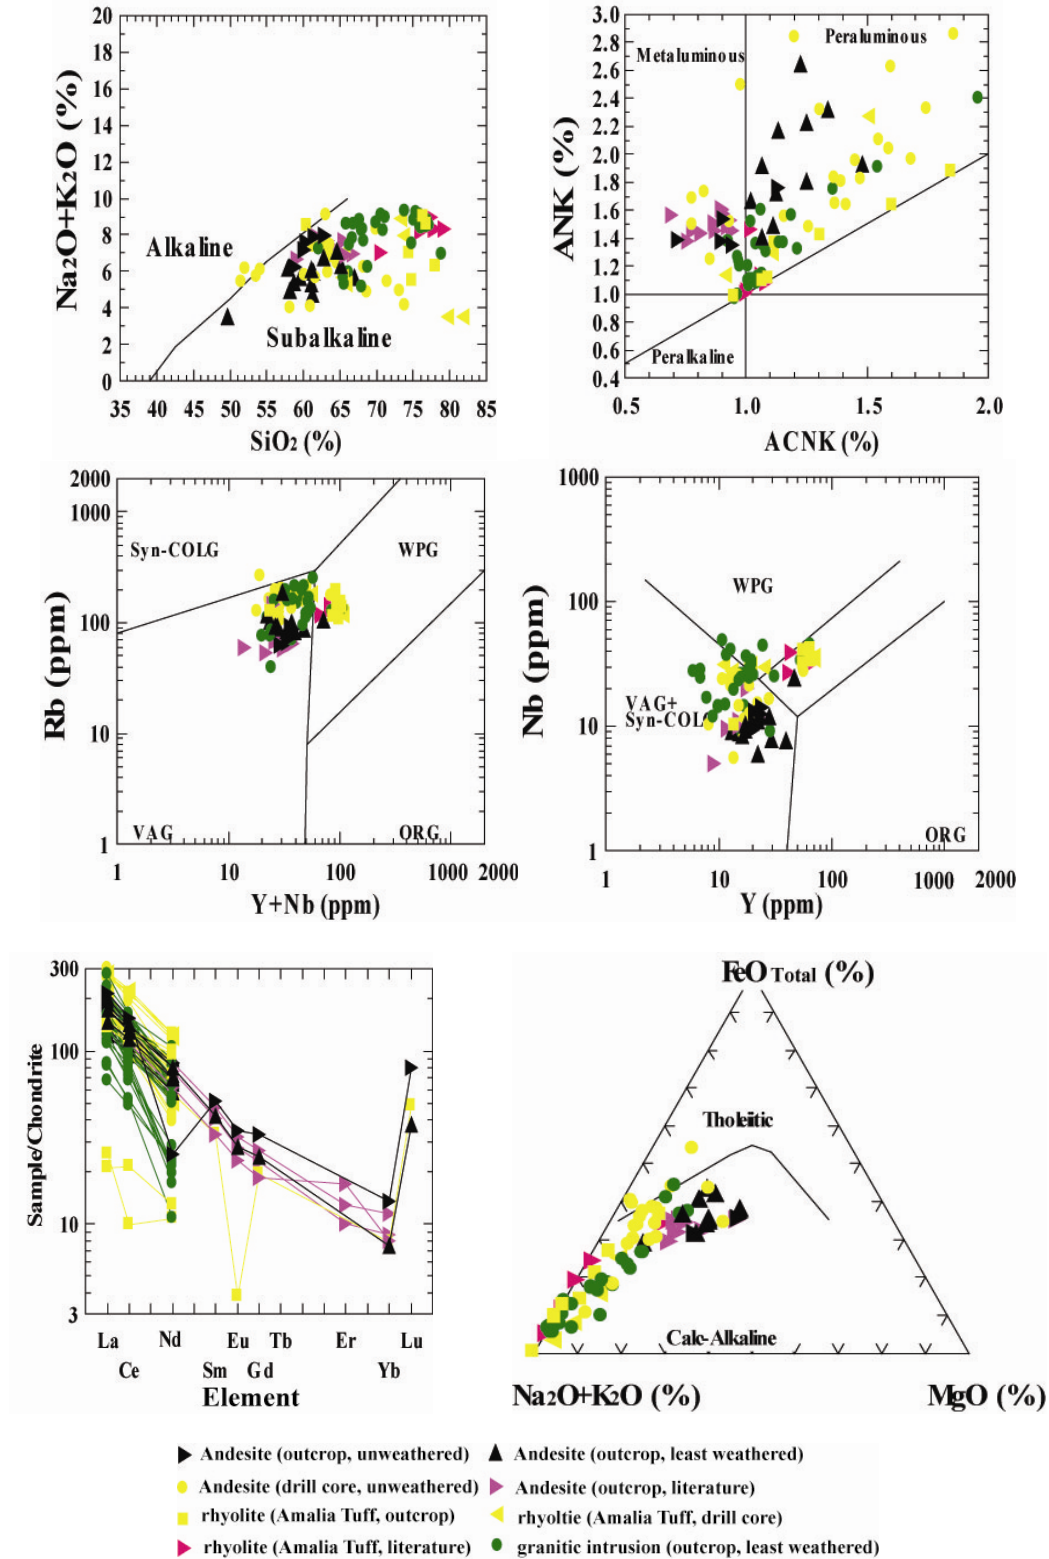

FIGURE 54. Lithogeochemical classification plots of relatively unweathered volcanic and intrusive rocks (including various hydrothermally-altered rocks) for the Questa-Red

River area. Chemical analyses are in the Appendix 1.  $ANK=Al_2O_3+Na_2O+K_2O$ .  $ACNK=Al_2O_3+CaO+Na_2O+K_2O$ .

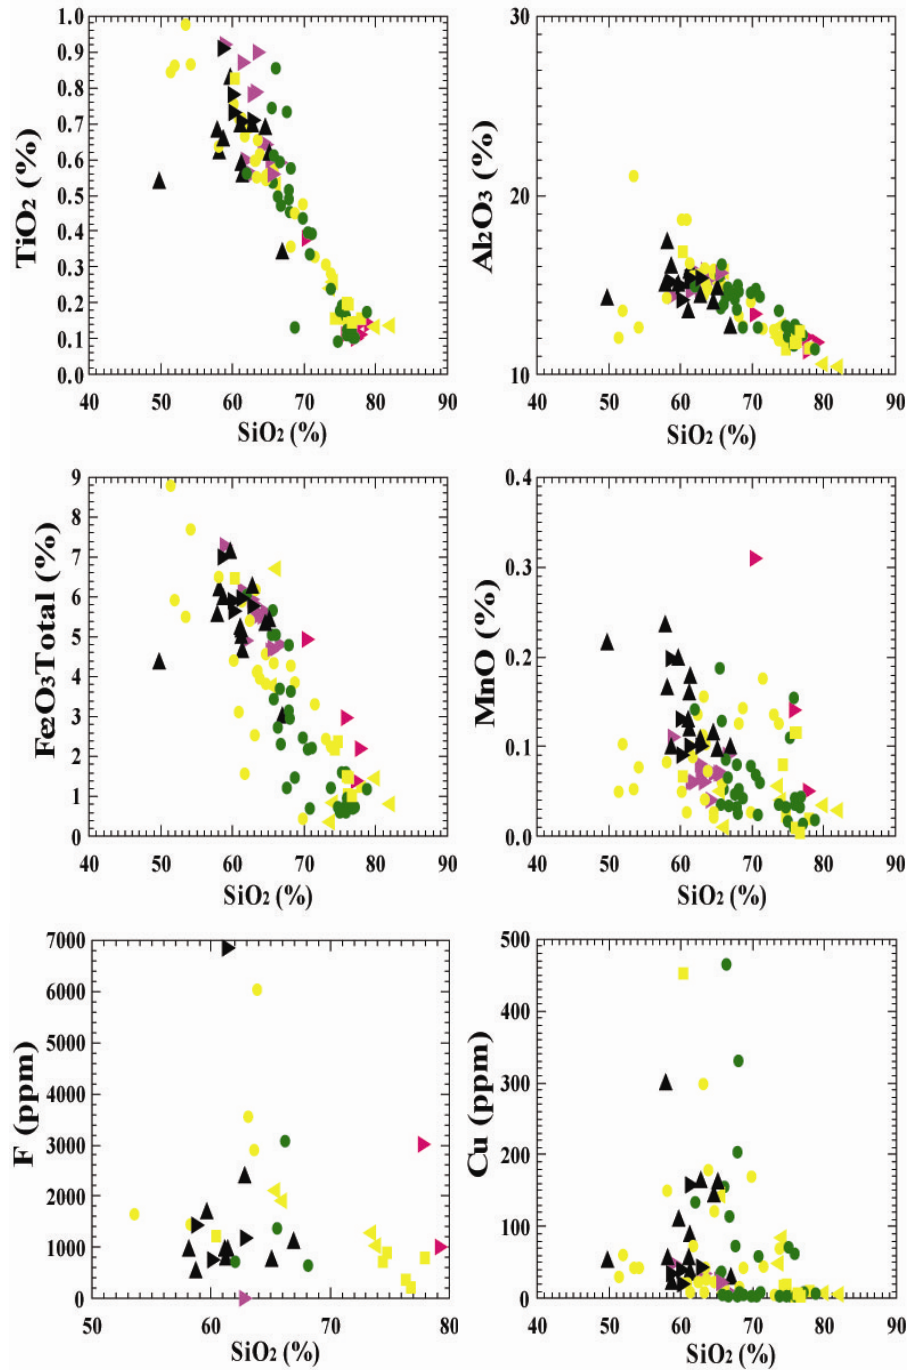

FIGURE 55. Scatter plots of selected elements and  $SiO_2$  of relatively unweathered volcanic and intrusive rocks (including various hydrothermally-altered rocks) for the Questa-Red River area. Chemical analyses are in Appendix 1. Key is in Figure 54.

Figure 56 shows the Questa-Red River fresh, relatively unweathered volcanic and intrusive rocks (including various hydrothermally-altered rocks) in terms of alteration

filter diagrams showing unaltered and hydrothermally altered fields (after Wilt, 1995; Keith and Swan, 1996; McLemore et al., 1999). Many of the drill-core samples show little chemical effect of the hydrothermal alteration, whereas a few of the fresh, unaltered samples plot in the alteration fields. This figure shows the complexity of pre-mining hydrothermal alteration effects on the chemistry and mineralogy of unaltered samples.

FIGURE 56. Graphs of relatively unweathered volcanic and intrusive rocks (including various hydrothermally-altered rocks) using alteration filter diagrams showing unaltered and hydrothermally altered fields (after Wilt, 1995; Keith and Swan, 1996; McLemore et al., 1999). Chemical analyses are in the project database. Major element oxides are in weight percent and trace elements are in parts per million (ppm). Key is in Figure 54.

### PARAGENESIS OF HYDROTHERMAL ALTERATION

Paragenesis is the sequence of hydrothermal events and is determined by detailed petrographic descriptions. Previous workers have described various aspects of the paragenesis of the hydrothermal alteration in the Questa deposit (Carpenter, 1968; Schilling, 1956; Bloom, 1981; Molling, 1983) and these results are summarized in Table 9 and Figures 57-59.

TABLE 9. Comparison of paragenesis of the vein and breccia deposits by different workers. q=quartz, b=biotite, K=K-feldspar, mo=molybdenite, f=fluorite, ru=rutile, py=pyrite, cc=calcite, cp=chalcopyrite, sp=sphalerite, gn=galena, rh=rhodocrosite, gy=gypsum, mh=malachite, lm=limonite, s=sericite. Ross et al. (2002) describes the paragenesis only of the main MHBx mineralizing event.

FIGURE 57. General paragenesis of mineralization and alteration (from Molling, 1968). MHBx event is the main mineralizing event, which is described in detail by Ross et al. (2002) in Table 9 and Figure 58.

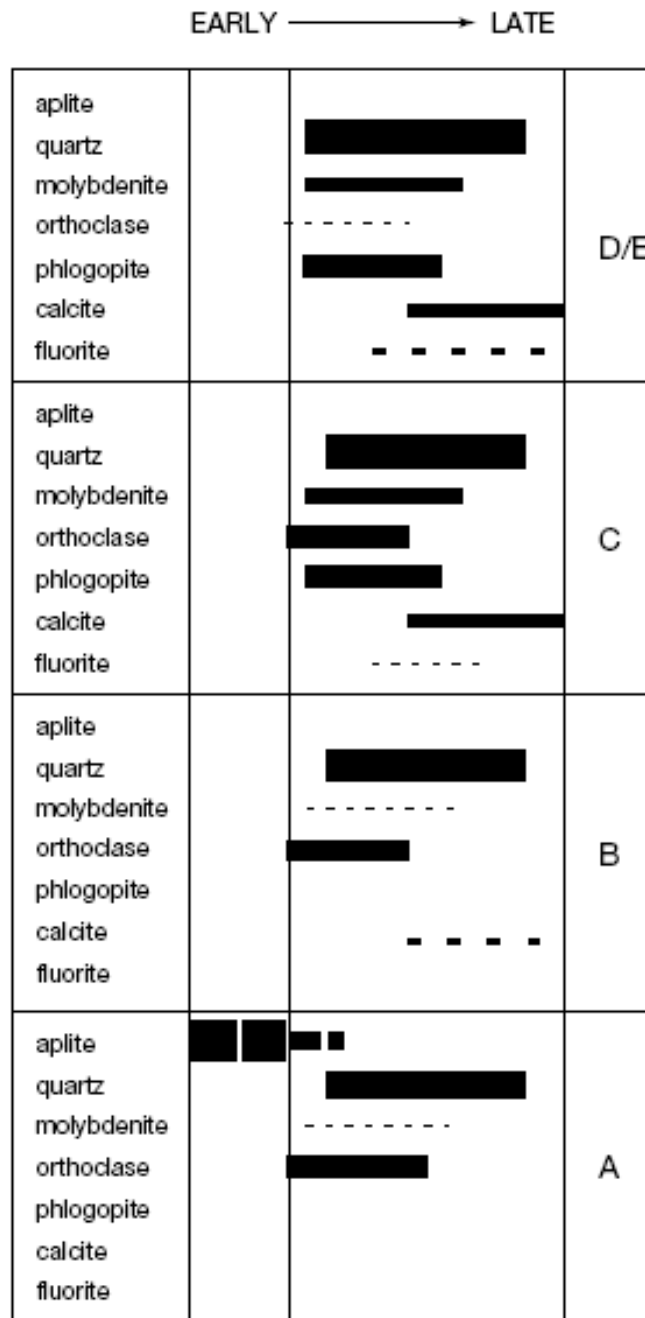

FIGURE 58. Paragenesis of the Questa breccia ore deposit (from Ross et al., 2002). A-E represents the different breccia facies.

FIGURE 59. Paragenesis of the Questa mineral deposit and alteration (from Meyer and Leonardson, 1990).

### SUMMARY

- Chemically, the volcanic rocks in the Questa-Red River area are calc-alkaline, metaluminous to peraluminous igneous rocks.
- The rhyolite (Amalia Tuff) has more quartz and little to no epidote and chlorite compared to the andesite.
- The rhyolite (Amalia Tuff) typically has higher SiO<sub>2</sub>, K<sub>2</sub>O, Rb, Nb, less TiO<sub>2</sub>, Al<sub>2</sub>O<sub>3</sub>, Fe<sub>2</sub>O<sub>3</sub>T, MgO, CaO, P<sub>2</sub>O<sub>5</sub>, and Sr than the andesite.
- Little, if any, unaltered rocks (i.e. primary magmatic) went into the Questa rock piles.

- The rock pile samples are a mixture of two or more rock types that were variably hydrothermally altered. GHN is a mixture of rhyolite (Amalia Tuff) and andesite.
- The rocks that went into the Questa rock piles were hydrothermally altered before mining, which resulted in large variations in mineralogical and chemical composition.
  - Amphiboles, pyroxenes, and feldspars were replaced by biotite and albite during alteration.
  - Biotite, hornblende, pyroxenes were hydrothermally altered to chlorite, sericite, smectite, illite, and mixed layer clays (prophyllitic alteration).
  - Feldspars show varying degrees of hydrothermal alteration to illite, kaolinite, smectite, quartz, mixed layer clays (QSP overprinting prophyllitic alteration).
  - Many rocks were silicified, and this silicification was accompanied by the addition of 1-2 stages of pyrite, illite, calcite, and/or gypsum.

TABLE A1-2. Chemical composition of relatively unweathered andesites (including various hydrothermally-altered rocks) from the Questa-Red River area obtained from this study. SWI=Simple Weathering Index define in McLemore et al. (2008a); a SWI  $\leq$  is fresh (unweathered) to least weathered. Major oxides are in weight percent and trace elements in parts per million (ppm).

TABLE A1-5. Chemical composition of relatively unweathered Amalia Tuff from the Questa-Red River area from Dillet and Czamanske (1987), Lipman (1988), Johnson et al. (1989), P. Lipman, written communication (2007) and this project. Major oxides are in weight percent and trace elements in parts per million (ppm).
