New Mexico Geology (NMG) publishes peer-reviewed geoscience papers focusing on New Mexico and the surrounding region. We also welcome submissions to the Gallery of Geology, which presents images of geologic interest (landscape images, maps, specimen photos, etc.) accompanied by a short description.

Published quarterly since 1979, NMG transitioned to an online format in 2015, and is currently being issued twice a year. NMG papers are available for download at no charge from our website. You can also subscribe to receive email notifications when new issues are published.

Rare Earth Elements (REE) Deposits in New Mexico: Update

Virginia T. McLemore, New Mexico Bureau of Geology and Mineral Resources, New Mexico Institute of Mining and Technology, Socorro, NM 87801 ginger@nmbg.nmt.edu

Abstract

 Deposits of rare earth elements (REE) are located in New Mexico, but they have not been important exploration targets in past years because demand has been met elsewhere. However, with a projected increase in demand, New Mexico deposits are being re-examined for their REE potential. REE-Th-U veins are found in the Gallinas, Capitan, and Cornudas Mountains and Laughlin Peak-Chico Hills; all are associated with Tertiary alkaline to alkalic-calcic igneous rocks. A small amount of bastnaesite, a REE mineral, was recovered during processing of fluorite mined in the Gallinas Mountains. Resources in the Gallinas Mountains amount to at least 537,000 short tons of 2.95% total REE. Four types of deposits are found in the Gallinas Mountains: epithermal REE-F veins, Cu-REE-F veins, REE-F breccia pipes and iron skarn deposits. The abundance of REE and other unusual minerals in the Cornudas Mountains suggests that the area has potential for undiscovered deposits of REE, niobium, and zirconium. U.S. Borax sampled and drilled in the Chess Draw area and found up to 0.06% total REE in samples. Other types of REE deposits in New Mexico include carbonatites in the Lemitar and Chupadera Mountains, Laughlin Peak-Chico Hills, Lobo Hill, and Monte Largo (Sandia Mountains). Disseminated Y-Zr deposits in Proterozoic syenite and nepheline syenite are known at Pajarito Mountain on the Mescalero Apache Indian Reservation near Ruidoso, where one sample contained 6,869 ppm total REE. In 1990, Molycorp, Inc. reported historic resources of 2.7 million short tons grading 0.18% Y2O3 and 1.2% ZrO2 as disseminated eudialyte. The U.S. Bureau of Indian Affairs drilled five holes in 2014 and results are pending. Two additional deposit types have potential for REE in New Mexico: (1) Cretaceous heavy mineral, beach-placer sandstone deposits and (2) pegmatites. Drilling of one of these deposits, the Apache Mesa (formerly the Stinking Lake) beach-placer sandstone deposit in the Jicarilla Indian Reservation is expected to occur in the fall of 2015. Exploration has occurred in the Lemitar, Gallinas, and Cornudas Mountains for hydrothermal vein deposits. Many challenges, including permitting, face these industries in supplying REE elements. Most REE deposits are radioactive, although they contain less uranium and thorium than uranium mines, but will require special handling of the mine waste. Future development of these commodities will be challenging and more research is required to fully understand the REE potential in New Mexico.

Table 1—Description of rare earth elements (REE) (from Taylor and McClennan, 1985; Samson and Wood, 2005; Rudnick and Gao, 2005; Castor and Hedrick, 2006; and Hedrick, 2009). * Promethium does not occur naturally.

Introduction

Overview

Before 2010 most Americans never heard of rare earth elements (REE), except maybe in high school chemistry class when studying the periodic table of elements (Table 1). However, in April 2010, China announced that it would impose immediate export quotas on REE in order to address environmental issues at their REE mines, regulate illegal REE mining operations, and to provide for a sustainable REE production and supply for China (i.e., monopoly, Gambogi and Cordier 2010). This announcement triggered an increase in price for REE and some panic buying. Then, in late September 2010, China halted exports of REE to Japan; the Japanese industry is a significant consumer of REE, particularly for production of electric/hybrid automobiles and...
consumer electronics (Table 2). Although China reinstated REE exports to Japan in early November 2010 and has since dropped their export quotas, these incidents placed the phrase “rare earth elements” in recent headlines and resource planners, politicians, investors, and journalists throughout the world began to examine the future supply of REE. Today, China has lowered the prices of REE and there is very little active exploration outside of China. The deposits being mined and developed outside of China are struggling due to low REE prices and low investment funding. However, since REE are required for many green energy technologies, the industry will recover in the future and eventually new mines will be needed to meet this demand.

Rare earth elements (REE) include the 15 lanthanide elements (atomic number 57-71), yttrium (Y, atomic number 39), and scandium (Sc, atomic number 21; Table 1) and are commonly divided into two chemical groups, the light REE (La through Eu) and the heavy REE (Gd through Lu, Sc, and Y). REE are lithophile elements (elements enriched in the crust) that have similar physical and chemical properties, and, therefore, occur together in nature. However, REE are not always concentrated into deposits that are economical to mine and only a few deposits in the world account for current production (Committee on Critical Mineral Impacts of the U.S. Economy 2008; Hedrick 2009; Long et al. 2010). Thorium (Th), uranium (U), niobium (Nb) and other elements typically are found with REE. Most deposits are radioactive because of their Th and U content, although not as radioactive as uranium mines.

REE have many specialized applications in industry (Table 2), and for many applications there is no known substitute (Naumov 2008; Hedrick 2009). The U.S. once produced enough REE for U.S. consumption, but since 1999 more than 90% of the REE required by U.S. industry have been imported from China (Haxel et al. 2002). However, the projected increase in demand for REE in China, India, U.S., and other countries has resulted in increased exploration and ultimate production from deposits in the U.S. and elsewhere.

REE deposits have been reported from numerous areas in New Mexico (Fig. 1), but were not considered important exploration targets because demand in past years has been met by other deposits in the world. However, with the projected increase in demand, these areas in New Mexico are being re-examined for their REE potential. The purposes of this report are to (1) summarize the resource potential for REE in New Mexico, (2) update earlier compilations by McLemore et al. (1988a, b), Adams (1963), Long et al. (2010), and McLemore (2014a, 2015a), and (3) suggest areas in the state for future exploration.

For the purposes of this report, a REE occurrence is defined as (1) past production of REE minerals, (2) whole-rock chemical analysis of greater than 1,000 ppm total REE, 500 ppm Y, or 100 ppm Sc, or (3) REE minerals found in sufficient quantities to be considered a potential mineral resource. This is a summary of a larger, more extensive report in preparation. Data used in this report have been compiled from a literature review, field examination, and unpublished data by the author.

Table 3—REE production from New Mexico deposits.
Types of REE deposits in New Mexico

Alkaline igneous rocks

Many alkaline igneous rocks, typically of syenite or granite composition, have higher concentrations of REE than other types of igneous rocks. Alkaline rocks are defined as rocks with Na$_2$O+K$_2$O>0.3718(SiO$_2$)-14.5 (MacDonald and Katsura 1964) or rocks with mol Na$_2$O+mol K$_2$O>mol Al$_2$O$_3$ (Shand 1951). Peralkaline rocks are particularly enriched in heavy REE, Y, and Zr. Some alkaline igneous rocks in the world contain potential economic REE deposits, and REE, Zr, Be, Nb, Ta, and other elements reside in accessory minerals that are disseminated in the alkaline igneous rock, which can be difficult to separate and process.

Disseminated Y-Zr deposits in syenite are found at Pajarito Mountain (Fig. 1). Several varieties of syenite, nepheline syenite, and alkaline igneous rocks in New Mexico have been identified as potential hosts for REE deposits. The Bureau of Indian Affairs drilled five holes in the Pajarito Mountain Y-Zr deposit on the Mescalero Apache Indian Reservation near Ruidoso in 2014. The NMBGMR has recently investigated REE deposits in veins and breccia pipes in the Gallinas Mountains, episyenites in the Caballo, Burro, and Zuni Mountains, and Cretaceous beach placer sandstone deposits in the San Juan Basin. New Mexico mines produced small amounts of REE as early as the 1940s from some pegmatite deposits in San Miguel, Santa Fe, Rio Arriba, and Taos Counties in northern New Mexico in Grant County in southwestern New Mexico and from the Gallinas Mountains in Lincoln County vein deposits (Table 3).
The term episyenite in the Caballo, Burro, and Zuni Mountains (Riggins 2014; with alkaline rocks, especially Cambrian-Ordovician episyenites with alkaline rocks, especially Cambrian-Ordovician episyenites, are a historic resource. Additional feasible studies are required to confirm this.

Figure 3—View looking southwest across Caballo Lake showing REE-bearing fine-grained episyenite (foreground) in the Northern Caballo granite in the Caballo Mountains.

Other areas in New Mexico have potential for REE associated with alkaline rocks, especially Cambrian-Ordovician episyenites in the Caballo, Burro, and Zuni Mountains (Riggins 2014; Riggins et al. 2014). The term episyenite is used to describe altered rocks that were desilicated and metasomatized by alkali-rich fluids (Leroy 1978; Recio et al. 1997). These metasomatic rocks in the Caballo, Burro, and Zuni Mountains were erroneously called syenites and alkali granites, but are actually metasomatic in origin and not primary igneous rocks. Episyenites are similar to rocks formed by fenitization and are also called fenites by some geologists. Fenitization is the alkali-metasomatism associated with carbonatites or alkaline igneous activity (LeBas 2008). However, we are reluctant to use the term fenite for these rocks in the Caballo, Burro, and Zuni Mountains because a carbonatite or alkaline magma source has not been observed at the surface in these areas. Episyenites also are found at Lobo Hill where episyenites, carbonatites, and lamprophyres have been mapped and sampled (McLemore et al. 1999).

The Cambrian-Ordovician alkaline magmatic event is well-documented in southern Colorado and New Mexico and is characterized by carbonatites, episyenites, lamprophyres, and other alkaline rocks dated between 664 and 450 Ma (McLemore et al. 1999; McMillan and McLemore 2004). REE disseminations in episyenites in the Caballo, Burro, Zuni Mountains, Lobo and Pedernal Hills are associated with this Cambrian-Ordovician magmatic event. The episyenites, which are nonfoliated, non-metamorphosed igneous rocks, cross cut Proterozoic foliations and are enriched in REE, U, Th, Nb, and other elements.

McLemore (1986), McLemore et al. (1988a, b, 2012), Riggins (2014), and Riggins et al. (2014) briefly described the known REE-Th-U and Nb episyenite deposits in the Red Hills, Pedernal Hills, Longbottom Canyon, and Apache Gap areas of the Caballo Mountains. The episyenites are spotty, discontinuous tabular bodies, narrow lenses, and breccia zones along faults, fractures, and shear zones in Proterozoic rocks (Fig. 3). Selected samples of episyenites from the Red Hills area in the Caballo Mountains contain as much as 20,000 ppm Th, 1,600 ppm U, 500 ppm Nb, 5,000 ppm Y, 600 ppm Be, 7,500 ppm Ga, and 200 ppm La. Some episyenites are enriched in heavy REE (Fig. 4).

Carbonatites

Carbonatites are carbonate-rich rocks of apparent magmatic derivation containing more than 50% magmatic carbonate minerals and less than 20% SiO₂ (Woolley and Kempe 1989; LeMaitre 1989, 2002; Verplanck et al. 2014), and typically are found in zoned complexes consisting of alkaline igneous
and/or carbonatite stocks, ring dikes, and cone sheets (Fig. 5). Carbonatites generally contain REE, U, Th, Nb, Ta, Zr, Hf, Fe, Ti, V, Cu, Sr, and are composed of calcite, dolomite, apatite, magnetite, vermiculite, and barite (Singer 2000). Typically, carbonatites are found in continental shields and continental rift environments. Fenitization is the predominant alteration associated with carbonatites; fenites are the altered rocks produced by fenitization. The Mountain Pass carbonatite is the largest economic carbonatite in North America, where bastnaesite was produced from 1954 to 2002 and in 2012 to present. Current reserves at Mountain Pass are estimated at more than 20 million metric tons of ore grading 8.9% total REE oxide (Castor 2008).

Carbonatite localities in New Mexico include the Lemitar and Chupadera Mountains, Laughlin Peak-Chico Hills, Lobo Hill, and Monte Largo (Sandia Mountains) in New Mexico (Fig. 1). Although carbonatites have not been found in the Gallinas Mountains, they are suspected to occur in the subsurface based on mineralogy and alteration (McLemore 2010a). Compositionally, the carbonatites in New Mexico are sövites, rauhaugites, and silicocarbonatites. The dikes are typically 1–5 ft wide (Fig. 6) and up to 1,500 ft long, and contain anonymously high concentrations of REE (Fig. 7), U, Th, and Nb.

REE-Th-U hydrothermal veins

REE-Th-U hydrothermal vein and breccia deposits (Staatz 2000) consist of various Th and REE minerals and are commonly associated with alkaline igneous rocks and carbonatites. REE-Th-U veins are associated with Tertiary alkaline igneous rocks in New Mexico in the Gallinas, Capitan, and Cornudas Mountains and Laughlin Peak-Chico Hills (Fig. 1). REE-Th-U vein and breccia deposits in New Mexico are typically found as tabular bodies, narrow lenses, and breccia zones along faults, fractures and shear zones. They are a few feet to 1,000s of feet long, as much as 10 ft wide, and can be discontinuous along strike, with varying grades and mineralogy. Globally, REE-Th-U veins are typically associated with carbonatites and alkaline rocks (Fig. 5).

Past production of bastnaesite has come from the Gallinas Mountains (Table 3). Four types of deposits characterize the Gallinas Mountains: epithermal REE-F veins, Cu-REE-F veins, REE-F breccia pipes and iron skarn deposits (McLemore, 2010a). District zonation is defined by Cu-REE-F (±Pb, Zn, Ag) hydrothermal veins that form the center of the district, surrounded by REE-F hydrothermal veins (McLemore 2010a). The magmatic-hydrothermal breccia pipe deposits form a belt partially surrounding the veins and contain the highest gold values, as much as 1,707 ppb (0.05 oz/short ton) Au as reported by Schreiner (1993) and McLemore (2010a). Iron skarns formed at the top and edge of the trachyte/syenite body and are likely the earliest stage of mineralization. The iron skarns are probably related to the REE-F and REE-F-Cu veins and breccias because they typically contain bastnaesite and fluorite and are similar in
REE and other trace element geochemistry (Fig. 8; McLemore 2010a). Fenites exhibit light REE enriched chondrite-normalized REE patterns (Schreiner, 1993). The mineralogy in the Gallinas Mountains is diverse and includes fluorite, quartz, barite, pyrite, iron oxides and accessory bastnaesite, calcite, chaledony, galena, bornite, chalcocite, pyromorphite, anglesite, chrysocolla, malachite, and azurite and rare agardite (yttrium-arsenic oxide), mimetite, wulfenite, vanadinite, metatorbernite, cerussite, among others (Perhac 1970; Demark 1980; Demark and Hlava 1993; McLemore 2010a; Vance 2013). Resources in the Gallinas Mountains amount to at least 537,000 short tons of 2.95% total REE (not NI-43-101 compliant; Schreiner 1993). A genetic model is summarized by intrusion/extrusion of crustal-derived igneous source rock in an extensional terrain possibly related to an alkaline-carbonatite complex with mineralization related to mixing of magmatic-hydrothermal and formation fluids (Vance, 2013).

Although there has been no mineral production from the Laughlin Peak district, three types of mineral deposits have been identified: (1) carbonatites, (2) breccia pipes, and (3) Th-REE hydrothermal veins (McLemore 2015a, b). Radioactive carbonatite dikes have the chemical composition of predominantly ferruginous calcic-carbonatite, with some calcio-carbonatite (also known as calcite carbonatite or sövite) and magnesio-carbonatite (also known as dolomite carbonatite or beforsite) and contain <1.6% total REE (Fig. 7, 9). The radioactive Th-REE veins cut Cretaceous sedimentary rocks and Tertiary volcanic flows, dikes and sills, strike predominantly west to northwest with steep north or south dips, and are less than 900 ft long and less than 3 ft wide. Crandallite, xenotime, thorite, and brookite are the predominant REE minerals and contain <1.2% total REE (Fig. 9) and <165 ppb Au. The radioactive intrusive breccia pipes consist of various iron and manganese oxide-stained, igneous rock fragments in a fine-grained siliceous and carbonate matrix of quartz and feldspar. The total REE is less than 3,017 ppm. The breccia pipes also contain as much as 5,900 ppm F, 9,050 ppm Ba, 535 ppm Nb, 54 ppm U, and 82 ppb Au. The Capitan pluton is associated with Th-REE (±Au, U) veins (Fig. 10), iron skarn and vein, and manganese vein and replacement deposits (McLemore 2014b). Iron and a small shipment of uranium ore were produced from the district. The Th-REE (±Au, U) veins occur along the western end of the pluton. One sample from the McCory prospect contains 8,133 ppm total REE (V.T. McLemore, unpublished data). Iron skarn and vein deposits are found along the western and northeastern portions of the pluton, whereas manganese deposits are along the northeastern portion of the pluton. The Th-REE (±Au, U) veins contain quartz, fluorite, adularia, hematite, calcite, fluorite, titane, allanite, thorite, chloride, and clay minerals (McLemore and Phillips 1991). They probably formed from late magmatic fluids evolved from the Capitan pluton as indicated by highly saline (as much as 80% eq. NaCl) fluid inclusions with homogenization temperatures of 500–600°C (Campbell et al. 1995).

The abundant REE and other unusual minerals in the Cornudas Mountains suggests that the area has potential for undiscovered deposits of REE, niobium, and zirconium (Schreiner 1994). U.S. Borax sampled and drilled in the Chess Draw area and reported up to 0.06% total rare-earth oxides,
10–1,400 ppm Nb, 10–3,000 ppm Zr, 230–13,000 ppm F. An analysis of a dike reported by McLemore et al. (1988a, b) contained 1,235 ppm Ce, 700 ppm La, 270 ppm Nd, and 242 ppm Y (Fig. 11). Analyses reported by Schreiner (1994) include as much as 3,790 ppm total REE (Fig. 11), 2,332 ppm Nb, 92 ppm Be, and 3,137 ppm F. Geovic Mining Corp. drilled in the Cornudas Mountains area in 2012, but results are unknown. Additional geologic, geochemical, and other exploration techniques are required to properly evaluate this area, especially in dikes and along intrusive contacts with the limestones.

**Pegmatites**

Pegmatites are coarse-grained igneous rocks, lenses, or veins with granitic composition, contain essential quartz and feldspar, and represent the last and most hydrous phase of crystallizing magmas (Page and Page 2000; Ercit 2005). Complex pegmatites include mineralogical and/or textural zoning. Pegmatites can contain a variety of economic minerals, including, mica, quartz, feldspar, and are enriched in Li, REE, Cs, Ta, Nb, Rb, Y, Sc, U, Th, Sn, B, Be and others. A number of pegmatites in New Mexico have yielded REE production in the past (Table 3), but in general pegmatites in New Mexico are poor mining targets, because the REE minerals are widely dispersed within throughout the pegmatite and are difficult to selectively mine and process.
Placer deposits

Placer deposits form by mechanical concentration of heavy minerals in a sedimentary environment, such as a river or beach. Ilmenite, rutile, magnetite, zircon, monazite and xenotime are the predominant economic minerals. Modern examples are Eneabba, western Australia and Odisha, India. Heavy mineral, beach-placer sandstone deposits is a specific type of placer deposit in New Mexico that contains REE. Heavy mineral, beach-placer sandstone deposits are concentrations of heavy minerals that formed on beaches or in longshore bars in a marginal-marine environment (Fig. 12; Houston and Murphy, 1970, 1977; McLemore, 2010b). Many beach-placer sandstone deposits contain high concentrations of Th, REEs (Fig. 13), Zr, Ti, U, Nb, Ta, and Fe. Detrital heavy minerals comprise approximately 50–60% of the sandstones and typically consist of titanite, zircon, magnetite, ilmenite, monazite, apatite, and allanite, among others. In New Mexico, these deposits are in Cretaceous sedimentary rocks (McLemore, 2010b). The Sanostee deposit is the largest known beach placer sandstone deposit in New Mexico (Fig. 14), but additional sampling and drilling are required to fully delineate the deposit and evaluate the REE resource potential (McLemore 2010b). Drilling of one of these deposits, the Apache Mesa (formerly known as Stinking Lake) deposit in the Jicarilla Indian Reservation, is expected to occur in the fall of 2015.

Another type of placer deposit in New Mexico are placer alluvial deposits formed down slope of REE-enriched Proterozoic pegmatites and granites. Residual placer deposits are reported from Ojo Caliente district in Rio Arriba County, where REE minerals are found in the alluvial sediments derived from pegmatites (Fig. 1).
Potential for New Mexico REE deposits

Increasing demand for cell phones, televisions, computers, iPods, video games, wind turbines, magnets, hybrid/electric cars, and solar panels results in increased demand for more REE. Mines that can be quickly permitted and which meet current regulations will likely be the next REE producers, even if better deposits are discovered later. However, REE mines, like all mine operations, will be productive for a limited time and new resources will have to be developed to meet the demand for REE in the future. New Mexico has some deposits that are in the early exploration stage and it will take years for these deposits to be developed, if they are economic. However, it is important to understand the REE potential in New Mexico, even if deposits are not produced in the next few years, because these resources could be important in the future and it takes many years to obtain mine permits and begin production.

There are no known substitutes for REE for most applications. New research is ongoing to develop technologies that will require less REE (Gambogi and Cordier 2010). Manufacturers are finding ways to be more careful about how they use REE. Just as aluminum cans became thinner as the price of that metal soared, companies will learn to make better use of the available REE.

The best potential sources for exploration for REE in New Mexico are 1) the disseminated Y-Zr deposits in syenite are found at Pajarito Mountain, 2) carbonatites, and 3) REE-Th-U hydrothermal vein and breccia deposits, particularly in the Gallinas Mountains, Laughlin Peak, and Cornudas Mountains districts. Strategic Resources Ltd. drilled in the Lemitar Mountains in 2011 and Gallinas Mountains in 2011–2012. Geovic Mining Corp. drilled in the Cornudas Mountains area in 2012. BE Resources Inc. announced that the Apache Warm Springs beryllium deposit in rhyolite contains anomalous REE (McLemore 2012), but has since dropped the project. Additional surface sampling and staking of mining claims throughout New Mexico has been done by various other companies. New Mexico pegmatites typically are too small to be currently mined for REE. However, residual placers from the pegmatites could have future potential. REE also are found in Cretaceous beach-placer sandstone deposits in the San Juan Basin in northern New Mexico, but these deposits also are too small to be mined economically today. Additional work is required on the episyenites to evaluate their potential, especially for heavy REE.

Acknowledgments

This report is part of on-going studies of mineral resources and the geology of carbonatites and alkaline igneous rocks in New Mexico, supported by the New Mexico Bureau of Geology and Mineral Resources, L. Greer Price, former Director and State Geologist. Recent research on episyenites in the Caballo and Burro Mountains was funded by the USGS Mineral Resources External Research Program (award number G12AP20051), NMBGMR, New Mexico Geological Society, and Department of Mineral Engineering (NMMIT). The NMBGMR also was recently awarded a contract by the Jicarilla Indian Tribe to examine the Cretaceous beach placer deposits at Apache Mesa near Stinking Lake, Rio Arriba County. Karen Kelly and Keith Long reviewed this manuscript and offered many suggestions to improve it. I would like to thank the many colleagues and students who contributed to and reviewed manuscripts over the years that much of this work is based upon.
